(Dated: December 28, 2022)

A simple method for presenting dynamic transition between Fresnel and Fraunhofer diffraction zones is considered. Experiments are conducted on different apertures and diffraction patterns are photographed at various distances between the screen and the aperture. Diverging lens is introduced into the experimental setup to provide good quality large diffraction patterns. Fresnel and Fraunhofer diffraction patterns and dynamic transition between them can be easily obtained on a distance of few meters, what gives an opportunity to use our setup as a lecture experiment. Experimental results for square aperture are shown and discussed.

I. INTRODUCTION

Fresnel and Fraunhofer diffraction and shapes of diffraction patterns appear as an important part of any optics lecture. It is often accompanied by presentation of the phenomenon, but this includes only Fresnel or Fraunhofer diffraction on common and simple apertures. It is mainly because these patterns can be quite easily calculated, so that one can easily compare theoretical and experimental results.

Our aim is to show the rarely presented but very interesting effect: the dynamic transition between Fresnel and Fraunhofer diffraction zones.

II. FRESNEL AND FRAUNHOFER DIFFRACTION ZONES

Diffraction can be classified as Fresnel or Fraunhofer (also called far field diffraction). In Fraunhofer diffraction the distance between the aperture and the screen is big enough to treat the wavefront as planar. In Fresnel diffraction the wavefront has to be treated as a curved surface, and the geometry of the setup becomes important.

A simple criterion^[1] may be formulated to assess the validity of various approximations. We consider monochromatic light source and assume that phase of the incident wave is the same at each point on the aperture. Denoting the characteristic size of the aperture by d (ie. its diameter), considering a point at a distance L from the aperture and using light of wavelength λ , the diffraction type can be described by a dimensionless parameter α :

$$\alpha = \frac{\lambda L}{d^2} \quad (1)$$

Generally, when $\alpha \gg 1$, we can use the Fraunhofer approximation. For example, with $\alpha = 1$, $\lambda = 650$ nm

and an aperture with diameter of $d = 1$ mm, we can estimate the distance as $L \approx 1.5$ m. Thus the screen should be perhaps $5L \approx 7.5$ m from the aperture to get a proper Fraunhofer diffraction pattern. Obviously, such a big distance is difficult to achieve in a lecture hall or classroom. On the other hand, Fresnel diffraction can be observed for $\alpha \leq 1$, so observing both types of diffraction on the same aperture may be quite complicated - the Fresnel image is very small and hence cannot be properly demonstrated. It is even more difficult to show the transition between them over such a big distance - one would have to move the aperture or the screen, what may cause a considerable loss in picture quality.

Let us now consider a diverging lens placed between the aperture and the screen. Because the aperture is relatively small, we can assume that the light rays passing through the lens are initially parallel. Then, using the lens equation and from the geometry of the setup we can simply deduce the magnification of the image at the screen (see fig. 2). Hence $\frac{1}{x} + \frac{1}{y} = \frac{1}{f}$, for $x \rightarrow \infty$, we get $y = f$, and from fig. 2 we get the relation:

$$Y = y_0 \left(1 + \frac{L}{|f|} \right) \quad (2)$$

The term standing near y_0 is obviously greater than 1. As the distance to the screen decreases (so that $L \ll f$), the magnification converges to 1.

Hence, by introducing a diverging lens into the experimental setup, we can get larger images from a small aperture. That in fact eliminates the problem of long distances and makes it possible to present dynamic change of the pattern while moving the lens between the aperture and the screen.

III. EXPERIMENTAL SETUP

The experimental setup (fig.1) consisted of He-Ne laser (5) as a monochromatic light source with wavelength $\lambda = 650$ nm, an aperture (4) and a screen (2), made of semi-transparent parchment, which allowed to observe on the back of the screen (1). This appears to be the

*Electronic address: mklis@fuw.edu.pl

best way to observe the pattern and take photographs because the light goes straight into the camera and the image is symmetrical. Any error in the screen position or aperture adjustment would result in degeneration of the image. The main difference between our setup and the standard one is the use of a movable diverging lens. That allows to observe a transition between the two types of diffraction without moving the screen or the aperture and ensures good quality images.

Thus, relatively small apertures (ca. 1 mm) could be used in the experiment, that shifts the Fraunhofer zone to closer distances. On the other hand, Fresnel pattern was very small, but this problem has been solved by using the diverging lens to show magnified image on the screen. The size was larger, although the quality was lower. We have used distances of about 3-5 meters. The lens had to be quite big. We have used one of focal length $f = -30$ cm and diameter of about 10 cm.

The apertures were obtained by exposing the aperture image (prepared in a vector graphics programme) on a transparent foil with high resolution (in our case it was 4000 dpi). The foil can be exposed in any photo lab.

Photographs were taken with the use of a digital reflex camera. As the light intensity on the screen rapidly decreases with the distance between the aperture and the lens, photographs have been taken at various exposure times, up to 20 seconds.

IV. DIFFRACTION IMAGES

The successive photographs 3(a)-3(f) present images of transition between Fresnel zone and quasi-Fraunhofer diffraction pattern for a square aperture. It is not an exact Fraunhofer image (for this, we would need bigger distances) but the image obtained at maximal distance does not differ significantly from the far-field image, what can be easily proved by placing the screen even further. The images were obtained by moving the lens from the aperture towards the screen. The best way to demonstrate the transition is putting a video camera behind the screen and connect it to a multimedia beamer. It provides big and sharp images, what makes them accurate for demonstrating purpose. The photographs have inverted colours to make the structures more visible, so the brighter areas in the photographs correspond to the darker zones in the real image.

The photograph 3(a) presents a typical Fresnel diffraction image. The grid-like structure inside a square is due to the bending of light rays on the borders of the aperture. There are lots of local minimums and maximums of light intensity due to constructive and destructive interference inside the square shape. Light intensity rapidly decreases outside the square.

In the photograph 3(b) the number of gratings is smaller. They are wider and we can also observe that the structure of the image changes - it still shows the symmetries, but the light intensity outside the square

does not decrease so rapidly.

In the image 3(c) we can observe the formation of a cross. Image 3(d) shows even clearer cross-like structure, both outside and inside. We can clearly see that two bright stripes get closer to merge completely in image 3(e).

The blurred structure in the middle of the picture is due to the fact that the centre of the image is much brighter than the other regions and during a long exposure time it receives much more light. We are now two-thirds of a way from the aperture to the screen. The limbs are clearly visible and we can also see their subtle structure - fringes. Placing the lens very close to the screen or completely removing it, we get an image similar to 3(f).

This is a classical Fraunhofer diffraction image. The limbs consist of clear fringes, and their intensity does not decrease rapidly as we recede from the central point. Also the regions between the limbs have an interesting structure, shown in figure 4. The whole image preserves the symmetries of the aperture. The structure of these regions is predicted by the theoretical description of Fraunhofer diffraction. We can look at this image as a product of two single slit diffraction patterns, as described in Pain's textbook [2].

More of our diffraction images, including diffraction on simple shapes (ie. multiple circular dots in various configurations) and also fractal apertures, like Sierpiński gasket or Koch curve, are available on the Internet: www.fuw.edu.pl/~mklis.

V. CONCLUSIONS

We have presented an experimental setup which allows to show a dynamic transition between Fresnel and Fraunhofer diffraction. Thanks to the use of a diverging lens we were able to observe both types of diffraction on the same aperture in a relatively small setup, which makes it particularly useful for lecture demonstrations.

Moreover, making new apertures is easy and available to almost everyone. It can be an interesting experiment to investigate transition patterns for common shape apertures, like slits or circular holes, as well as for more complicated ones. One can also consider symmetries of diffraction images and their connection with the geometry of apertures.

The presented images are only to show that it is possible to obtain high-quality diffraction images in school conditions, but the real transition is much more attractive to see. One can observe the dynamic changes of structure, the exact process of image formation.
