(Dated: October 2024)

Deep neural network architectures often consist of repetitive structural elements. We introduce a new approach that reveals these patterns and can be broadly applied to the study of deep learning. Similar to how a power strip helps untangle and organize complex cable connections, this approach treats neurons as additional degrees of freedom in interactions, simplifying the structure and enhancing the intuitive understanding of interactions within deep neural networks. Furthermore, it reveals the translational symmetry of deep neural networks, which simplifies the application of the renormalization group transformation—a method that effectively analyzes the scaling behavior of the system. By utilizing translational symmetry and renormalization group transformations, we can analyze critical phenomena. This approach may open new avenues for studying deep neural networks using statistical physics.

I. INTRODUCTION

Deep learning has demonstrated remarkable performance across a diverse array of fields. Despite this success, its theoretical foundations are still in their early stages, largely due to the numerous degrees of freedom and the complexity of the deep neural network (DNN) system [\[1,](#page-9-0) [2\]](#page-9-1). Statistical physics is frequently used to understand complex systems with many degrees of freedom. Consequently, it is natural to expect that applying a statistical physical approach to deep learning will uncover new insights into the field.

Numerous studies have explored the connection between deep learning and statistical physics, driven by the complexity of their behaviors. Several key research areas have been thoroughly documented in the review [\[3\]](#page-9-2). Some studies address the relationship between deep learning models employing the gradient descent method and the Gibbs distribution, with the cost function acting as the Hamiltonian under specific conditions [\[4–](#page-9-3)[10\]](#page-9-4). In the past, the spin glass model was proposed as a physical framework with similarities to deep learning systems, where the parameters serve as the degrees of freedom [\[10–](#page-9-4) [13\]](#page-9-5). Some earlier research suggested that neurons act as the degrees of freedom in deep learning systems, with Hopfield's and Little's work, as well as the Boltzmann machine, being well-known examples [\[12,](#page-9-6) [14–](#page-9-7)[18\]](#page-9-8).

Some studies have attempted to explain the success of deep learning through the renormalization group (RG) transformation. The hierarchical structure of DNN has inspired efforts to explore the connection between DNN and RG transformation. In these studies, unimportant scaled data diminishes as it passes through layers of neurons [\[19](#page-9-9)[–25\]](#page-9-10). Additionally, the RG transformation has been suggested as a way to describe the training process of deep learning models [\[26\]](#page-9-11). An effective method for

initializing DNNs from the perspective of RG has been proposed, and the scaling behavior of information is discussed in Ref. [\[27\]](#page-9-12). The RG transformation demonstrates its true power when applied to the study of phase transitions and critical phenomena in systems. Some studies have explored connections between phase transitions, critical phenomena, and deep learning [\[4,](#page-9-3) [6,](#page-9-13) [8,](#page-9-14) [11,](#page-9-15) [20,](#page-9-16) [27–](#page-9-12) [32\]](#page-9-17).

Recently, intriguing phenomena have emerged in deep learning, particularly involving the (broken) neural scaling law—a principle that seems consistent across different systems. Several papers have studied the neural scaling law, with some suggesting that this behavior may be linked to phase transitions [\[33](#page-9-18)[–42\]](#page-10-0).

Despite significant efforts to establish a connection between deep learning and statistical physics, a concrete and general understanding of this relationship has yet to be achieved. This challenge partly stems from the complexity of the cost function. In DNNs, the iterative structure and non-linear activation functions cause the perturbative expansion of degrees of freedom—the synaptic weights and biases—to generate infinitely many nonnegligible higher-order terms. In physics, solving problems of this nature often involves identifying underlying symmetries. For instance, translation symmetry plays a key role in analyzing the Ising model [\[43\]](#page-10-1). Similarly, recognizing symmetries in a model is crucial for understanding its behavior.

In this paper, we develop a method to reformulate the cost function into a form that reveals symmetry, thereby reducing its complexity. We call this the 'dynamic neuron' approach. It can be understood as a decoupling technique that introduces additional degrees of freedom—the neurons in the bulk layers—coupled with the original degrees of freedom. After decoupling these degrees of freedom, the system exhibits translation symmetry similar to that of the Ising model. In a specific case, we show that this approach yields a Hamiltonian resembling that of the Ising model or the spin glass model. Due to this symmetry, many tools of statistical physics, including RG transformations and correlation lengths, become applicable to DNNs.

FIG. 1. A deep neural network with $N = 2$ and $M = 2$, where N is the width of each layer, and M represents the depth of the DNN. For simplicity, the bias term b has been omitted.

The remainder of this paper is organized as follows. In Sec. [II,](#page-1-0) we provide a brief review of the deep learning and the statistical physics approach. In Sec [III,](#page-2-0) we introduce the dynamic neuron approach and a new Hamiltonian to analyze DNNs. In Sec. [IV,](#page-4-0) we present an example of the RG transformation using our new method. Critical phenomena are discussed in Sec. [V.](#page-6-0) The summary and discussion are provided in Sec. [VI,](#page-7-0) and a discussion of the spin glass model limit is included in App. [A.](#page-8-0)

II. FUNDAMENTALS OF DEEP LEARNING

Before proceeding further, we overview the basic concepts of deep learning and its statistical physical approach. This section is largely based on Refs. [\[8,](#page-9-14) [44,](#page-10-2) [45\]](#page-10-3).

A DNN is a system inspired by the brain [\[46,](#page-10-4) [47\]](#page-10-5). It consists of neurons, synaptic weights and synaptic biases, with neurons organized into layers. The i -th neuron in the $(m+1)$ -th layer, denoted as $h_i^{(m+1)}$, is influenced by all neurons in the m-th layer, which are connected via synaptic weights $W_{ij}^{(m)}$ and synaptic biases $b_i^{(m)}$. (See Fig. [1.](#page-1-1)) This relationship is described by the following equation:

$$
h_i^{(m+1)} = \sigma \left(\sum_j W_{ij}^{(m)} h_j^{(m)} + b_i^{(m)} \right)
$$

$$
\equiv \sigma_i^{(m)}.
$$
 (1)

In this formula, σ represents a nonlinear function known as the activation function.^{[1](#page-1-2)} The repetitive calculation of Eq. [\(1\)](#page-1-3) determines the value of each neuron, starting from the input (initial layer) $x = h^{(0)}$ and eventually reaching the output (final layer) $z = h^(M)$.

Simply put, deep learning is a method for approximating an unknown function using a DNN. The process of building a neural network from a given dataset is called training. There are several types of deep learning classified by their training methods, but we will focus on supervised learning for the sake of simplicity. In supervised learning, the machine is trained to give a good approximation for a set of examples, known as a training dataset. The training dataset X consists of L data vectors $x^{[l]}$, $l = 1, 2, \dots, L$, and their corresponding label vectors $y^{[l]}$. For simplicity, we will often omit [l], provided it does not cause confusion.

The goal of the training process is to minimize the discrepancy between the label $y^{[l]}$ and the output of the DNN $z^{[l]}$ by adjusting the synaptic weights $W_{ij}^{(m)}$, and biases $b_i^{(m)}$.

The discrepancy between the label and the output is typically measured using the L^2 - or L^1 -norm, referred to as the cost function or training error. The cost function using the L^2 L^2 -norm is given as²

$$
C = \sum_{i,l} \left(y_i^{[l]} - z_i^{[l]} \right)^2.
$$
 (2)

A popular method for reducing the cost function is gradient descent. In each step of adjusting the synaptic weights and biases, the gradient of the cost function is calculated, and the synaptic weights and biases are adjusted by subtracting this value.

$$
\Delta W_{ij}^{(m)} = -\eta \frac{\partial C}{\partial W_{ij}^{(m)}}, \qquad \Delta b_i^{(m)} = -\eta \frac{\partial C}{\partial b_i^{(m)}}, \qquad (3)
$$

where the step size η determines the magnitude of the weight and bias updates. These equations show that the DNN is constructed by determining the values of the weights and biases, not the neurons. In other words, only the weights and biases are the degrees of freedom in the system, while the neurons serve as placeholders in Eq. (1) .

After the training of a DNN is complete, it is used for general data; this process is called inference. The main purpose of deep learning is to train a DNN that makes good inferences. Addressing inference presents many challenges, which we plan to discuss in future work.

From a physical perspective, Eq. [\(3\)](#page-1-5) represents the equation of motion for the system^{[3](#page-1-6)}. It is widely recognized that this equation of motion causes the system to conform to a Gibbs distribution [\[8\]](#page-9-14). Specifically, the probability distribution of encountering a particular

 $¹$ Typically, the sigmoid function or ReLU is used as an activation</sup> function. An example of the sigmoid function is $\sigma(x) = \frac{1}{1+e^{-x}}$, and for ReLU, it is $\sigma(x) = \max(x, 0)$.

 2 Although it is customary to define the cost function by dividing Eq. (2) by the number of data points L, we do not follow this convention. Since L can be absorbed into the step size, it does not affect our discussion.

³ In Eq. [\(3\)](#page-1-5), the step size can be interpreted as the time interval between weight updates. Since it does not influence the underlying physics, we set $\eta = 1$.

synaptic configuration W , b after a sufficiently long period of training is given by:

$$
P(W, b) = \frac{1}{Z}e^{-\beta C},\tag{4}
$$

where $\beta = \frac{1}{T}$, and T is the temperature of the deep learning system, which depends on the noise in deep learning [\[8\]](#page-9-14). We incorporate the factor $\frac{1}{L}$ from C into β . The partition function, denoted by Z , is defined as:

$$
Z \equiv \sum_{\{W,b\}} e^{-\beta C},\tag{5}
$$

where $\{W, b\}$ represents all possible configurations of synaptic weights and biases.

Any expectation value of observables can be calculated as follows:

$$
\langle O \rangle = \frac{1}{Z} \sum_{\{W, b\}} O e^{-\beta C}.
$$
 (6)

As one can see, the cost function C plays the role of the Hamiltonian. Therefore, it will be denoted as H from now on.

III. DYNAMIC NEURONS

As mentioned earlier, during training, the change in synaptic weights $W_{ij}^{(m)}$ and biases $b_i^{(m)}$ over time follows the equation of motion defined by the gradient descent. This indicates that synaptic weights and biases represent the system's degrees of freedom. The cost function, or Hamiltonian, governs the probability distribution of degrees of freedom after the training process.

$$
H_{\text{original}} = \sum_{i,l} \left(y_i^{[l]} - z_i^{[l]} \right)^2 \tag{7}
$$

where

$$
z_i^{[l]} = \sigma \Big(\sum_{i_1} W_{ii_1}^{(M)} \sigma \Big(\sum_{i_2} W_{i_1 i_2}^{(M-1)} - \cdots \sigma \Big(\sum_{i_M} W_{i_{M-1} i_M}^{(0)} x_{i_k}^{[l]} + b_i^{(0)} \Big) + b_i^{(1)} \Big) \cdots \Big).
$$
 (8)

In this Hamiltonian, the synaptic weights and biases are iteratively plugged into the activation function, as specified by Eq. [\(1\)](#page-1-3). Although DNNs are usually described as shown in Fig. [1,](#page-1-1) this iterative structure reveals highly complex interactions between degrees of freedom, as depicted in the upper figure of Fig. [2.](#page-3-0) This complexity can be understood by considering the Taylor series expansion of the activation function, which involves complicated products of synaptic weights and biases. In particular, even the distant degrees of freedom can interact. Additionally, synaptic weights and biases from different layers contribute differently to H , increasing the asymmetry and complicating the analysis further. To apply various concepts from statistical physics, we need to compute the partition function through the following integral:

$$
Z = \int dW d\theta \exp[-\beta H_{\text{original}}]. \tag{9}
$$

This integration is challenging to compute, as the Hamiltonian consists of intricate terms involving synaptic weights and biases. Therefore, managing the Hamiltonian and the partition function in their original forms is immensely difficult.

To address this difficulty, we promote the neurons $h^{(m)[l]}$ to additional dynamic degrees of freedom and ensure that Eq. [\(1\)](#page-1-3) is dynamically satisfied. Instead of using iterated activation functions, we introduce a series of Dirac delta functions and simplify the exponent to the absolute square as follows:

$$
Z = \int dW d\theta \, dh \prod_{i,l,m} \exp\left[-\beta \left(y^{[l]} - h^{(M)[l]}\right)^2\right] \qquad (10)
$$

$$
\delta \left(h_i^{(m+1)[l]} - \sigma_i^{(m)[l]}\right).
$$

Here, i runs for the width, l runs for the data number, and m runs for the layer. We refer to these new dynamic degrees of freedom, $h^{(m)[l]}$, as "dynamic neurons." While this partition function appears straightforward, it does not yet simplify the computation.

To further evaluate the calculations, we employ an ap-proximation of the Dirac delta function^{[4](#page-2-1)} as the limit of a Gaussian distribution:

$$
\delta(z) \approx \lim_{v \to 0^+} \frac{1}{v\sqrt{2\pi}} \exp\left[-\frac{z^2}{2v^2}\right].
$$
 (11)

Applying this approximation, the partition function becomes:

$$
Z = \int dW \, db \, dh \lim_{v \to 0^+} \left(\frac{1}{v\sqrt{2\pi}}\right)^n
$$

$$
\exp\left[-\beta \sum_{i,l} \left(y_i^{[l]} - \sigma_j^{(M)[l]}\right)^2 - \beta_v \sum_{i,l,m} \left(h_i^{(m+1)[l]} - \sigma_i^{(m)[l]}\right)^2\right],\tag{12}
$$

where $\beta_v = 1/2v^2$.^{[5](#page-2-2)}

⁴ Despite the name, the Dirac delta function is not a function but a distribution or generalized function. This means that the approximation may not be strictly valid in the rigorous sense, though it is frequently employed in the literature. We adopt this approximation because the partition function involves integration, and we expect it to yield accurate results once integrated.

 5 Although distinct values of v could be assigned to each term,

FIG. 2. Interactions in the original and new Hamiltonians. For simplicity, each layer includes only one neuron, and synaptic biases are omitted. The upper figure depicts the original Hamiltonian, while the lower figure illustrates the new Hamiltonian. Degrees of freedom are connected if a direct coupling exists between them. (Self-interactions are omitted in both cases.) Circles in the lower figure represent dynamic neurons, the newly introduced degrees of freedom.

We observe that incorporating the constraint terms reveals the internal structure of a DNN within the Hamiltonian framework. By defining the new Hamiltonian as

$$
H_{\text{new}} = \sum_{i,l,m} \lambda_m \left(h_i^{(m+1)[l]} - \sigma_i^{(m)[l]} \right)^2 \tag{13}
$$

with $\lambda_m = \beta_v/\beta$ except for $\lambda_M = 1$. We can denote Eq. [\(12\)](#page-2-3) in the typical way of describing the partition function,

$$
Z = \int dW \, db \, dh \exp[-\beta H_{\text{new}}].\tag{14}
$$

where the limit over v is omitted for simplicity. The form of this new Hamiltonian is the summation of interactions between the nearest layers (*m*-th layer and $(m + 1)$ -th layer). In other words, interactions in the new Hamiltonian are restricted to the nearest degrees of freedom following the same pattern, unlike the original Hamiltonian.

Physically, this approach can be viewed as a decoupling strategy. Dynamic neurons are introduced between the original degrees of freedom, effectively simplifying the complex interactions between weights and biases. These interactions are decoupled and replaced with simpler interactions between dynamic neurons and their nearest weights and biases, analogous to using power strips to organize and untangle cables. The structure of the new Hamiltonian is illustrated in the lower part of Fig. [2,](#page-3-0) where the original Hamiltonian's complex structure shown in the upper figure is decoupled.

Since Eq. [\(13\)](#page-3-1) is written as a sum of terms with the same form, the Hamiltonian is invariant under translation,

$$
h_i^{(m)[l]} \to h_i^{(m+1)[l]}, \quad \sigma_i^{(m)[l]} \to \sigma_i^{(m+1)[l]} \qquad (15)
$$

except at the boundaries (the first and last layers). This approximate symmetry is not easily identifiable in the original Hamiltonian given by Eqs. [\(7\)](#page-2-4) and [\(8\)](#page-2-5).

The emergence of this type of translation symmetry can simplify calculations and lead to interesting consequences. For example, in the one-dimensional and twodimensional Ising models, the transfer matrix can be calculated explicitly due to translational symmetry. Therefore, it is expected that the new Hamiltonian can be analyzed by utilizing this symmetry. As an example, we perform the renormalization group transformation in Sec. [IV.](#page-4-0)

This symmetry is approximate due to the system's boundaries. However, it is generally assumed that as the system size increases, the symmetry becomes more precise. Similarly, in a DNN with considerable depth, the symmetry becomes nearly exact. Since depth is regarded as a key factor in the success of deep learning [\[48–](#page-10-6)[52\]](#page-10-7), this approximate symmetry may offer insights into the role of depth in understanding neural networks.

The new Hamiltonian in Eq. [\(13\)](#page-3-1) is expressed as the sum of the original cost function (for $m = M$) and additional constraint terms, each multiplied by a constant λ_m (for $m \neq M$). This approach is analogous to the use of Lagrange multipliers in Lagrangian mechanics. Notably, similar terms arise when the Yang-Mills Lagrangian is quantized using the Fadeev-Popov procedure in quantum field theory [\[53\]](#page-10-8), although we will not discuss this further here.

Moreover, this system can be effectively described using principles from statistical physics, which are often

we assume v remains the same for all terms. If a limit exists as multiple distinct values of v approach 0, the same limit will be achieved when the values of v are set identically and approach 0. This can also be understood through the concept of a Lagrange multiplier. If we interpret β_v as the Lagrange multiplier, it imposes the constraint that the sum of the absolute square terms must vanish. For this to occur, each individual term must also vanish.

employed to uncover the macroscopic behavior of complex systems composed of similarly interacting units. With certain simplifying assumptions, this approach yields a Hamiltonian that closely resembles the spin glass model, a well-established framework in statistical physics.[6](#page-4-1) (See Appendix [A\)](#page-8-0). This approach offers a new method for applying the spin glass model to gradient descent-based training in DNNs.

IV. RENORMALIZATION GROUP TRANSFORMATION

Since the new Hamiltonian resembles well-known statistical models, we can apply statistical physics tools to analyze the training of DNNs. A promising method in statistical physics is the renormalization group (RG) transformation, which is widely used in fields such as condensed matter and high-energy physics. This technique systematically simplifies a system by progressively integrating out smaller-scale fluctuations, leading to a renormalized system with fewer degrees of freedom.

To understand how the components of the DNN function, we apply the RG transformation with respect to depth using our new Hamiltonian, as shown in Fig. $3⁷$ $3⁷$ $3⁷$ We begin by examining a simple scenario under specific assumptions. While these assumptions may oversimplify the system, potentially differing from actual DNNs, this example is designed to illustrate how the RG transformation can be applied to DNN within the context of the new Hamiltonian.

(i) The system consists of one neuron per layer $(N = 1)$ with a large depth $(M \text{ is large})$, and the training dataset

FIG. 3. RG transformation applied to the DNN using the dynamic neuron approach, resulting in reduced network depth.

contains a single data point $(L = 1)$. This assumption significantly reduces the system's computational complexity. However, the following discussions can be easily extended to systems with larger N or L , aside from the resulting increase in computational complexity.

(ii) The activation function is the Heaviside step function:

$$
\sigma(x) = \begin{cases} 0 & x < 0 \\ 1 & \text{otherwise} \end{cases}
$$
 (16)

Although the Heaviside step function is rarely used in modern DNNs due to its zero gradient, it was employed in earlier models and applications [\[46,](#page-10-4) [54\]](#page-10-9).

(iii) The weights W and biases b are restricted to values of -1 or 1, and the neurons h are limited to values of 0 or 1. While, in theory, h should be integrated over all possible values, we expect the Gaussian-like behavior of the partition function to constrain h to values near 0 or 1. Although in general deep neural networks, W and b can take arbitrary real numbers, we restrict their values here for simplicity. Interestingly, recent research has explored neural networks where parameters are similarly restricted to discrete values, such as -1 , 1 or -1 , 0, 1. Despite these limitations, that model appears to achieve good performance [\[55,](#page-10-10) [56\]](#page-10-11).

Given the restrictions on the available values, integration in the partition function is replaced by summation. Thus, the partition function for this example is written as:

$$
Z = \sum_{\{W, b, h\}} \exp[-\beta H] \tag{17}
$$

where the summation is over all possible values of W, b , and h. Since we are considering the case with $N = 1$ and $L = 1$, the new Hamiltonian in Eq. [\(13\)](#page-3-1) can be expressed as a sum:

$$
H = \sum_{m} \lambda_m H_m \tag{18}
$$

where each H_m has the common form:

$$
H_m = \left[h^{(m+1)} - \sigma \left(W^{(m)} h^{(m)} + b^{(m)} \right) \right]^2.
$$
 (19)

As discussed in Sec. [III,](#page-2-0) the Hamiltonian exhibits translational symmetry similar to that of the Ising model. Consequently, we can apply the RG transformation in a manner similar to its application in the Ising model. One approach involves summing over $W^{(m)}$, $b^{(m)}$, and $h^{(m)}$ for even-numbered layers in the partition function. After performing this summation, the partition function describes a system with fewer degrees of freedom. This real-space RG transformation method is known as decimation [\[57,](#page-10-12) [58\]](#page-10-13), and the translational invariance plays a crucial role in performing the decimation.[8](#page-4-4)

⁶ Several approaches have already introduced spin glass models to analyze DNNs under various assumptions [\[10](#page-9-4)[–17\]](#page-9-19).

 7 After an RG transformation, the system's degrees of freedom are $\,$ reduced, making the Hamiltonian primarily distance-dependent along the depth direction. This complicates applying the RG transformation with respect to the width, as maintaining the Hamiltonian's form during such a transformation is challenging.

⁸ Decimation is generally avoided for systems with dimensions

Extracting the terms related to $W^{(m)}$, $b^{(m)}$, and $h^{(m)}$ from the partition function, we have

$$
Z_m = \sum_{\{W^{(m)}, b^{(m)}, h^{(m)}\}} \exp[-\beta H_{m+1} - \beta H_m]. \tag{20}
$$

This summation is finite and can be calculated without difficulty:

$$
Z_m = 3u^{-2}u^{2h+2\sigma} + u^{-1}(u^{2\sigma} + 2u^{2h}) + 2
$$
 (21)

where

$$
h = h^{(m+1)},
$$

\n
$$
\sigma = \sigma(W^{(m-1)}h^{(m-1)} + b^{(m-1)}),
$$

\n
$$
u = e^{\beta_v}.
$$
\n(22)

By taking the logarithm, we obtain the Hamiltonian of the renormalized system, denoted as H' :

$$
-\beta H'_m = \ln[3u^{-2}u^{2h+2\sigma} + u^{-1}(u^{2\sigma} + 2u^{2h}) + 2].
$$
 (23)

By making use of the restricted configuration, where $h^2 = h$ and $\sigma^2 = \sigma$, we can express the renormalized Hamiltonian in polynomial form:[9](#page-5-0)

$$
-\beta H'_m = h\sigma \ln(3u^2 + 3u + 2)
$$

+ $(1 - h)\sigma \ln(u + 2u^{-1} + 5)$
+ $h(1 - \sigma) \ln(2u + u^{-1} + 5)$
+ $(1 - h)(1 - \sigma) \ln(3u^{-2} + 3u^{-1} + 2)$
= $h\sigma \ln \frac{(3u^2 + 3u + 2)(2u^2 + 3u + 3)}{(u^2 + 5u + 2)(2u^2 + 5u + 1)}$ (24)
+ $h^2 \ln \frac{u(2u^2 + 5u + 1)}{2u^2 + 3u + 3}$
+ $\sigma^2 \ln \frac{u(u^2 + 5u + 2)}{2u^2 + 3u + 3}$
+ (constant).

In general, suppose that our Hamiltonian takes the following form:

$$
-\beta H = \sum_{m} \left(Ah\sigma + Bh + C\sigma + D \right). \tag{25}
$$

Under the RG transformation, the constant term in the Hamiltonian only affects the non-singular part of the free energy and is typically ignored when calculating the critical properties of the system.

FIG. 4. RG flow near the fixed points $e^A = 1$, demonstrating that RG flows converge to the plane composed of fixed points.

$$
A' = \ln\left[\frac{2 + 2e^{A+C} + e^{A+B} + 3e^{2A+B+C}}{2 + 2e^{A+C} + e^B + 3e^{A+B+C}}\right]
$$

$$
\frac{2 + 2e^C + e^B + 3e^{B+C}}{2 + 2e^C + e^{A+B} + 3e^{A+B+C}}\right]
$$

$$
B' = B + \ln\frac{2 + 2e^{A+C} + e^B + 3e^{A+B+C}}{2 + 2e^C + e^B + 3e^{B+C}}
$$

$$
C' = C + \ln\frac{2 + 2e^C + e^{A+B} + 3e^{A+B+C}}{2 + 2e^C + e^B + 3e^{B+C}}
$$

The fixed points are the points that the renormalized system is equal to itself. By obtaining the solutions (A, B, C) of the equation

$$
(e^{A'}, e^{B'}, e^{C'}) = (e^A, e^B, e^C), \tag{27}
$$

the fixed points (A^*, B^*, C^*) of this system can be found. The exponents are used to simplify the calculations. The fixed points are given as

$$
e^{A^*} = 1\tag{28}
$$

for arbitrary values of e^{B^*} and e^{C^*} . Figure [4](#page-5-1) illustrates the RG flows near these fixed points. The RG flows converge to the fixed points, indicating that there is no phase transition.

Since the couplings are real, there are no fixed points other than those given in Eq. [\(28\)](#page-5-2). However, if we assume that e^{A^*}, e^{B^*} , and e^{C^*} can be negative, we can find another fixed point at

$$
e^{A^*} = 3, e^{B^*} = -\frac{2}{3}, e^{C^*} = -\frac{1}{3}.
$$
 (29)

The RG flow near this fictitious fixed point is shown in Fig. [5,](#page-6-1) where we observe that the RG flows diverge from this point. This fixed point appears unphysical since it can only be achieved when the couplings are imaginary. Nevertheless, we anticipate that more general and complex deep learning models, beyond our simplifying assumptions (i)–(iii), will exhibit unstable fixed points, or

higher than one because it fails to account for the renormalization of the magnitude of the degrees of freedom, preventing it from achieving a true fixed point in higher dimensions.

 9 This approach of representing complex functions as polynomials is also observed in the RG transformation of the Ising model.

FIG. 5. Diverging RG flow near the fictitious fixed point $(e^{A^*}, e^{B^*}, e^{C^*}) = (3, -2/3, -1/3)$. For visibility, $e^{C} = -1/3$ is fixed for all flows.

critical points, where RG flows diverge within realistic coupling regions.[10](#page-6-2) Near unstable fixed points, critical phenomena can be discussed. The critical phenomena and scaling laws near this fictitious fixed point are studied in Sec. [V.](#page-6-0)

Let us discuss the physical meaning of the RG transformation in the dynamic neuron approach. As discussed earlier, the introduction of dynamic neurons results in additional terms, $\lambda_m H_m$, which reflect the constraints,

$$
H_m = \left[h^{(m+1)} - \sigma \left(W^{(m)} h^{(m)} + b^{(m)} \right) \right]^2 = 0, \quad (30)
$$

equivalent to Eq. [\(1\)](#page-1-3). This constraint explains the relationship between the nearest degrees of freedom. After the RG transformation, the degrees of freedom in the mth layer are integrated out, and the renormalized Hamiltonian H'_m is composed of the nearest degrees of free-dom.^{[11](#page-6-3)} As Eq. (30) reflects the constraints between the nearest degrees of freedom, the vanishing conditions of the renormalized Hamiltonian

$$
H'_m = 0 \tag{31}
$$

can be interpreted as new constraints between the nearest degrees of freedom in the renormalized system. As the depth of the DNN decreases by applying the RG transformation, new constraints for the system with reduced depth emerge. Therefore, the RG transformation suggests statistically equivalent constraints for the system with reduced depth. Theoretically, by applying these new constraints to the partition function, the introduced dynamic neurons can be integrated out. Subsequently, a renormalized DNN system without dynamic neurons can

be obtained. In general, after applying the RG transformation, the constraints often become more complex, leading to multiple solutions or analytically unsolvable equations. However, even if we cannot solve them explicitly, identifying these constraints can aid in understanding the structure of DNNs. In this sense, the dynamic neuron approach is a valuable tool for comprehending the nature of DNNs. This argument can be generalized without relying on the simplifying assumptions (i)–(iii).

The discussions in this section are schematically summarized in Fig. [6.](#page-6-5) Since the RG transformation is a useful technique in statistical physics, we aim to use it to analyze DNNs. However, the direct application of the RG transformation to DNNs is challenging, so we applied the dynamic neuron approach. Due to the translational symmetry that emerges from the dynamic neuron approach, the RG transformation can be applied much more easily. The RG transformation of a DNN using the dynamic neuron approach suggests new constraints for the system with reduced depth. By applying these constraints, a renormalized DNN system can be obtained.

V. CRITICAL PHENOMENA

Critical phenomena are dramatic behaviors that occur near critical points and are crucial in understanding phase transition physics. One key feature of critical phenomena is the scaling law, where physical quantities exhibit power-law behavior. A remarkable aspect of critical phenomena is universality, which means that many systems can exhibit the same scaling laws despite microscopic differences, provided they share key characteristics.

To make predictions about the scaling properties of general deep learning, we further study the fictitious fixed point from the example in the previous section, even though it is not physical. By considering the linear ap-

FIG. 6. This diagram illustrates how to develop a renormalized DNN using the dynamic neuron (DyN) approach. Although not a rigorous explanation, it effectively conveys the essential concept. By introducing dynamic neurons, we obtain a new description of the DNN, and from the advantages of this new description, we derive a renormalized DNN with dynamic neurons. By applying constraints, the dynamic neurons can be integrated out, resulting in a renormalized DNN.

¹⁰ This reasoning is grounded in insights from statistical physics. For instance, while the one-dimensional Ising model lacks a phase transition at any finite temperature, the two-dimensional Ising model does undergo such a transition.

¹¹ Since the m-th layer is integrated out, the $(m-1)$ -th and $(m+1)$ th layers become the nearest layers.

proximation of the RG transformation near the critical point, we can analyze the critical properties of the system.

$$
\vec{K}' - \vec{K}^* = \mathcal{R}(\vec{K}) - \mathcal{R}(\vec{K}^*)
$$

$$
\approx \frac{d\mathcal{R}}{dK}|_{K=K^*}(K - K^*),
$$
 (32)

where $\vec{K} = (e^A, e^B, e^C), \vec{K'} = (e^{A'}, e^{B'}, e^{C'}), \vec{K}^* =$ $(3, -2/3, -1/3)$, and $\mathcal{R}(\vec{K}) = \vec{K}'$ denotes the function of RG transformation. Then, near \vec{K}^* , the RG transformation can be approximated as follows:

$$
\begin{bmatrix} e^{A'} - 3 \ e^{B'} + 2/3 \ e^{C'} + 1/3 \end{bmatrix} \approx \begin{bmatrix} 2 & 0 & 0 \ 0 & 2 & 0 \ 0 & 0 & 2 \end{bmatrix} \begin{bmatrix} e^A - 3 \ e^B + 2/3 \ e^C + 1/3 \end{bmatrix}
$$

$$
= \begin{bmatrix} p^{y_A}(e^A - 3) \\ p^{y_B}(e^B + 2/3) \\ p^{y_C}(e^C + 1/3) \end{bmatrix},
$$
(33)

where $p = 2$ denotes the ratio between the depth of the original and renormalized systems. The y_A , y_B , and y_C determine the critical phenomena of the system. We can consider the continuum limit with respect to p. In other words, we can consider infinitesimal RG transformation from M to $p^{-1}M$ where $p = 1 + \epsilon$.

From Eq. [\(33\)](#page-7-1), we can find the scaling laws of observables near the fixed point. As an example, let us introduce the scaling of the correlation function. For simplicity, we explore the scaling laws under the conditions $B = B^*$ and $C = C^*$, though this argument can easily be generalized.

The correlation function of neurons is defined as

$$
G_h(h^{(m)}, h^{(n)}, A - A^*)
$$

= $\langle h^{(m)}h^{(n)} \rangle_H - \langle h^{(m)} \rangle_H \langle h^{(n)} \rangle_H$ (34)
= $G_h(m - n, A - A^*),$

where $\langle \cdot \rangle_H$ denotes ensemble average with respect to the Hamiltonian H^{12} H^{12} H^{12} . Note that the last equality holds due to translational invariance. As stated earlier, translational invariance was not readily apparent in the original cost function. This implies that our approach reveals the underlying correlating properties of deep learning.

The correlation length ξ is defined from the behavior of the correlation function, which means that

$$
G_h(m - n, A - A^*) \propto e^{-|m - n|/\xi} \tag{35}
$$

for sufficiently large $|m - n|$.

After the RG transformation, the difference in depth between two neurons decreases by the ratio p. Since we are calculating the correlation function of neurons h , the coupling constants associated with the neurons, B, affect the scaling of the correlation function. Furthermore, the dimension of the system d , along with the degree of freedom we are reducing, affects the RG transformation. In our example, we consider the RG transformation with respect to depth, so $d = 1$.

In general, the following scaling behavior can be found near the critical point:

$$
G_h\left(\frac{m-n}{p}, A'-A^*\right) = p^{2d-2y} G_h(m-n, A-A^*). (36)
$$

Equation [\(36\)](#page-7-3) is the core of the scaling law for the correlation function and correlation length.

Considering $p^{y_A}|A - A^*| = A_0$ for some positive constant A_0 , and substituting $p = (A - A^* / A_0)^{-1/y_A}$, one can conclude that

$$
G_h(m-n, A-A^*) \propto \Psi\left((m-n)\left|\frac{A-A^*}{A_0}\right|^{1/y_A}\right) \tag{37}
$$

for some function Ψ . For large $m - n$, we expect the correlation function to follow Eq. [\(35\)](#page-7-4), so we find the scaling law of the correlation length:

$$
\xi \propto |A - A^*|^{-1/y_A}.\tag{38}
$$

Now, considering that $r/p = r_0$ for some fixed distance r_0 , and repeating the same argument, one can conclude that

$$
G_h(m - n) \propto |m - n|^{-2d + 2y_B} \tag{39}
$$

near the critical point.

These scaling laws are frequently observed in various examples of critical phenomena in statistical physics. Further research from the statistical physics perspective could provide deeper insights into these phenomena.

VI. SUMMARY AND DISCUSSION

The statistical physical approach to deep learning has been explored in many studies, but there is no agreedupon description. Additionally, the dynamics of neurons have only been discussed in specific models, such as the Hopfield network and the Boltzmann machine, which differ fundamentally from typical deep learning systems [\[14,](#page-9-7) [15,](#page-9-20) [18\]](#page-9-8).

Our study introduced the dynamic neuron approach. In this approach, neurons are treated as dynamic variables of the system. We transformed the original Hamiltonian, where the degrees of freedom are synaptic weights and biases, into a new Hamiltonian with additional degrees of freedom—dynamic neurons.

The new Hamiltonian simplifies the interactions and reveals translational invariance. This symmetry, induced by the dynamic neuron approach, is approximate because the first and last layers are ignored. However, as the number of layers increases, the relative effects of the first and

¹² We can also define correlation functions for different variables, such as $G_{\sigma}(\sigma^{(m)}, \sigma^{(n)}, A - A^*)$.

last layers diminish, and the symmetry becomes better preserved. This observation could be related to a fundamental question about DNNs: why do they perform so well when their depth is large? Our approach might offer insights into many fundamental questions about deep neural networks [\[59\]](#page-10-14).

Additionally, the dynamic neuron approach highlights that the degrees of freedom—dynamic neurons, synaptic weights, and synaptic biases—interact primarily with their nearest neighbors. This interaction is intuitive, as neurons in a network communicate only with adjacent neurons to produce the final output. Consequently, the entire system can be understood by examining its individual components and their interactions.

We discussed the RG transformation and critical phenomena using a simple example of a DNN with dynamic neurons. Although it was a straightforward case, we demonstrated that well-known statistical approaches can be easily applied to DNNs using the dynamic neuron approach. RG transformations and critical phenomena are deeply studied topics in statistical physics with many physical implications. Finding connections between these implications and the properties of DNNs is very intriguing and promises rich outcomes.

Appendix A: Spin Glass

In this appendix, we illustrate how the new Hamiltonian in the dynamic neuron approach replicates key characteristics of spin glass models, a class of statistical models renowned for their complex energy landscapes and disordered states. While there are several formulations of spin glass models, we focus on the Edwards-Anderson model, a canonical example widely used in statistical physics [\[60,](#page-10-15) [61\]](#page-10-16):

$$
H = \sum_{i,j} J_{ij} s_i s_j + \sum_i K_i s_i,
$$
 (A1)

where s_i are spin degrees of freedom, which take values of 1 or -1 , and the coupling constants between spins J_{ij} are typically assumed to follow independent probability distributions, such as Gaussian or Bernoulli distributions. K_i is the coupling to magnetic fields which dependent on external magnetic field.

We apply certain conditions and assumptions to the new Hamiltonian presented in Eq. [\(13\)](#page-3-1). Suppose the activation function is the sigmoid function, so $|\sigma|$ and $|h|$ are likely smaller than 1. Also, introduce the regularization terms to restrict W and b from becoming too large.

Furthermore, we expect that the linear order expansion of the sigmoid function is a valid approximation.

The new Hamiltonian, without the constant term, is then given as:

$$
H = \sum_{i,j,l,m} \lambda_m W_{ij}^{(m)} h_i^{(m+1)[l]} h_j^{(m)[l]}
$$

+
$$
\sum_{i,l,m} \lambda_m b_i^{(m)} h_i^{(m+1)[l]}
$$

+
$$
\sum_{i,j,m} c_W (W_{ij}^{(m)})^2 + \sum_{i,m} c_b (b_i^{(m)})^2.
$$
 (A2)

where the last two terms are regularization terms. These regularization terms provide the Gaussian probability distribution for W and b and result in the Gaussian distributed coupling constants for the first two terms in the Hamiltonian. Then the first two terms of Hamiltonian are similar to the spin glass model with a space-varying external magnetic field with degrees of freedom h and coupling constants determined by W and b .^{[13](#page-8-1)}

¹³ One should note that despite these similarities, there are differences between spin glass models and the new Hamiltonian: (1) The couplings can vary in time, and (2) The spin degrees of freedom can take arbitrary values between −1 and 1.
