Abstract

Most of the matter in the universe is in the form of dark matter. However, dark matter has never been observed to interact with normal matter in laboratory experiments. ALPs – ultralight axionlike particles – are a class of dark matter models that are consistent with astrophysical constraints, and produce measurable signatures in the form of oscillating violations of discrete symmetries in nuclei. We report the first results from a search for oscillating parity-odd time-reversal-odd nuclear moments of 153 Eu ions in a crystal, which leads to an experimental constraint on the ALP-gluon coupling strength across a wide band of ALP masses.

Astrophysical observations indicate that the majority of matter in the universe is dark matter [\[1\]](#page-10-0). However, dark matter has only been observed to interact gravitationally with ordinary matter, and no other interactions with Standard Model particles have been measured [\[2\]](#page-10-1).

Out of the many models for the cold dark matter within galaxies, ultralight axionlike particles (ALPs) are a well-motivated and viable subset [\[3–](#page-10-2)[5\]](#page-10-3). When ALPs interact with gluons within atomic nuclei, they induce nuclear moments that are odd under parity (P) and time-reversal (T) symmetries, and that oscillate in time [\[6\]](#page-10-4). Experiments sensitive to P-odd T-odd nuclear moments – such as searches for permanent electric dipole moments (EDMs) of particles – can detect these oscillations. For example, broadband laboratory bounds on the ALP-gluon coupling strength in the mass range below 3×10^{-12} eV have been obtained from neutron EDM experiments [\[7,](#page-10-5) [8\]](#page-11-0). The $H f F^+$ electron EDM experiment [\[9\]](#page-11-1) and a series of frequency comparison experiments [\[10](#page-11-2)[–16\]](#page-12-0) also provide bounds, which, although less stringent than the bounds from neutron EDM experiments, nevertheless offer useful cross-checks using different physical systems.

In this work, we probe oscillatory P-odd T-odd nuclear moments using precision spectroscopy of octupole-deformed nuclei in a crystal (ONIX). Our measurement method builds upon the search for static nuclear T-violation proposed in Ref. [\[17\]](#page-12-1). We use europium-153 (nuclear spin $I = 5/2$), a stable isotope with an octupole-deformed nucleus that has a large, collectively enhanced, P-odd T-odd nuclear Schiff moment induced by ALPs [\[18,](#page-12-2) [19\]](#page-12-3).

Triply-charged europium ions doped into a yttrium orthosilicate crystal (Eu:YSO)

are located at non-centrosymmetric crystal sites, where their charge distribution is strongly electrically polarized by the neighboring ions in the crystal. In these trapped, polarized europium ions, the Schiff moment interacts with the electron density gradient near the nucleus, causing nuclear spin states to shift in energy. These characteristic energy shifts depend on the relative orientation of the nuclear spin vector, \vec{I} , and the electric dipole moment of the polarized atom, \vec{D} . Observation of an *oscillating* energy shift proportional to $\vec{I} \cdot \hat{D}$ is the signature of an oscillatory P-odd T-odd nuclear moment, such as would be produced by ALPs.

Crucially, Eu:YSO contains an equal number of Eu^{3+} sites with oppositely-directed \vec{D} vectors, distributed throughout the crystal. These sets of oppositely-polarized ions form two ensembles whose ALP-induced energy shifts oscillate precisely out of phase. Meanwhile, the shifts of these two ensembles due to magnetic fields (including stray fields and spurious backgrounds) are identical and in phase. Therefore comparing measurements between the oppositely-polarized ions provides an accurate means to separate ALP signals from magnetic-field-induced systematic errors [\[20\]](#page-12-4).

Furthermore, the narrow ${}^7F_0 \rightarrow {}^5D_0$ transition of Eu³⁺ enables optical state control of the europium ions, which leads to fast state preparation, low-noise readout of the nuclear spin states, and simultaneous interrogation of the oppositely-polarized ensembles. Finally, the large number of Eu^{3+} ions in available in the crystal results in high sensitivity to ALP signals.

To quantify the above discussion, we note that ALPs result in a time-varying value of the dimensionless $\bar{\theta}$ parameter of quantum chromodynamics (QCD) [\[6\]](#page-10-4).

$$
\bar{\theta}(t) = \frac{C_G a_0}{f_a} \sin\left(\frac{m_a c^2}{\hbar} t\right). \tag{1}
$$

Here C_G is the gluon coupling constant ($C_G = 1$ for the QCD axion) [\[9\]](#page-11-1), a_0 is the ALP field amplitude, f_a is the ultra-high energy scale associated with ALP formation, and m_a is the ALP mass [\[6\]](#page-10-4). The $\bar{\theta}$ parameter in turn creates a nuclear Schiff moment in 153 Eu given by

$$
\vec{\mathscr{S}}(t) = \mathscr{S}_{\bar{\theta}} \frac{\vec{I}}{|I|} \bar{\theta}(t), \tag{2}
$$

where $\mathscr{S}_{\bar{\theta}}$ is the ¹⁵³Eu Schiff moment per unit $\bar{\theta}$ [\[18,](#page-12-2) [19\]](#page-12-3).

In an electrically polarized Eu^{3+} ion with dipole moment \vec{D} , the effective Hamiltonian describing the T-odd energy shifts of the nuclear spin states is ${\cal H}_{\rm ALP}=-d_\mathscr{S}\vec{\mathscr{S}}\!\cdot\!\vec{\mathcal{E}}_{\rm eq},$ where $d_{\mathscr{S}} = 0.33 \times 10^{-17}~e\,{\rm cm}/e\,{\rm fm^3}$ is the ratio of the permanent atomic EDM to the nuclear Schiff moment for Eu $^{3+}$ [\[4\]](#page-12-5), and $\vec{\mathcal{E}}_{\mathrm{eq}}$ is the *equivalent electric field* that would have to be applied to the ion to induce in it a dipole moment \vec{D} . The magnitude of the equivalent electric field for the polarized Eu^{3+} ions in Eu:YSO crystal is estimated to be $\mathcal{E}_{eq} = 1.5$ GV/cm (see Supplemental Material Section I), aligned along the D1 axis of the YSO crystal (denoted as \hat{x} in the following).

Combining the equations above, the effective Hamiltonian for the nuclear spin states is

$$
\mathcal{H}_{\text{ALP}}(t) = (h \times 400 \,\text{kHz}) \left(\frac{\mathcal{S}_{\bar{\theta}}}{1 \, e \, \text{fm}^3} \right) \left(\frac{\mathcal{E}_{\text{eq}}}{1.5 \, \text{GV/cm}} \right) \frac{(\vec{I} \cdot \hat{x})(\vec{D} \cdot \hat{x})}{|I|} \, \bar{\theta}(t),
$$
\n
$$
= h \, W_T(\vec{I} \cdot \hat{x})(\vec{D} \cdot \hat{x}). \tag{3}
$$

In our experiment, the P-odd T-odd frequency shift due to $\mathcal{H}_{ALP}(t)$ is measured. The oscillating part of this frequency shift yields the ALP-gluon coupling strength C_G/f_a .

A schematic diagram of the experiment is shown in Fig. [1,](#page-4-0) and Fig. [2](#page-5-0) shows the relevant energy levels and their labels. Measurements were made on a YSO crystal doped with 153Eu^{3+} at 0.01% concentration. The crystal, 3.5 mm \times 4.0 mm \times 5.0 mm, was attached to a cold plate and maintained at 5 K. A pair of copper plates adjacent to the crystal were used to apply an electric field, \mathcal{E}_{dc} , along the \hat{x} axis. A coil was used to generate radio-frequency (rf) magnetic fields along the \hat{z} axis (parallel to the b axis of the crystal). This doubly-resonant coil was used to apply rf fields in a band around 119.2 MHz to drive the $(a, \bar{a}) \leftrightarrow (b, \bar{b})$ nuclear spin transition in the ⁷F₀ electronic ground state for state preparation, and to apply fields in a band around 141 kHz to drive the $b \leftrightarrow \bar{b}$ transition for precision spectroscopy. SmCo permanent magnets were used to apply a static magnetic field $\mathcal{B}_{dc} \approx 225$ G across the Eu:YSO crystal; we chose this value of \mathcal{B}_{dc} in order to adequately separate the $a - b$ and $\bar{a} - \bar{b}$ resonances around 119.2 MHz.

We probed ions at "site 1" in Eu:YSO, where the ${}^{7}F_0 \rightarrow {}^{5}D_0$ optical transition is at 580.04 nm [\[22\]](#page-12-6). The inhomogeneously-broadened linewidth of the optical transition in our sample was 700 MHz, and the linewidth of the spectral anti-holes used for our

FIG. 1. Apparatus schematic. Data was taken using laser absorption spectroscopy of the ${}^{7}F_{0} \rightarrow {}^{5}D_{0}$ transition in a Eu:YSO crystal, held at 5 K. The crystal was placed between a pair of electric field plates, contained within an rf magnetic field coil. A static magnetic field parallel to the electric field was applied using SmCo permanent magnets. The electric field and magnetic field direction is along the crystal D1 axis. The laser propagates through the crystal b axis and is polarized along the D1 axis.

measurements were typically 1 MHz. When an electric field is applied to the crystal, the spectral anti-holes for the oppositely-polarized ion ensembles shift in opposite directions, by an amount proportional to their respective orientations relative to the crystal axis, $\mathcal{D}=\hat{D}\cdot\hat{x}=\pm1.$ We used an electric field $\mathcal{E}_{\rm dc}=125\,\rm V\,cm^{-1},$ which produces a spectral shift $\Delta \nu = \mp 3.3 \text{ MHz}$ [\[3\]](#page-12-7) for the $\mathcal{D} = \pm 1$ ensembles, to distinguish the optical absorption features from oppositely-polarized ions and extract W_T .

The experiment sequence begins with an optical pumping pulse that sweeps through the ${}^{7}F_{0}$ $a, \bar{a} \rightarrow {}^{5}D_{0}$ c', \bar{c}' resonance [\[9\]](#page-12-8). This pulse clears out the population of spectroscopic classes that are unused in the experiment, and creates a flat background for absorption measurements. Next, \mathcal{E}_{dc} is turned on, and optical pulses tuned to the 7F_0 $a, \bar a\to{}^5D_0$ $c', \bar c'$ and 7F_0 $c, \bar c\to{}^5D_0$ $b', \bar b'$ resonances pump ions into the 7F_0 $b, \bar b$ states using the spectral hole burning methods described in Refs. [\[9,](#page-12-8) [25\]](#page-12-9). The electric field is turned off for the subsequent steps, so that the optical absorption features from the $D = \pm 1$ ions become separated by 6.6 MHz and can be separately measured. Optical probe pulses tuned to the ${}^7F_0 a$, $\bar{a} \to {}^5D_0 c'$, \bar{c}' , $\mathcal{D} = \pm 1$ resonances determine the background absorption level through the crystal for normalization. An adiabatic rf sweep across the $b \leftrightarrow a$ transition moves ions out of the b state, leaving ions initialized in the

FIG. 2. Energy levels of ¹⁵³Eu³⁺:YSO. The ground ⁷ F_0 and excited ⁵ D_0 electronic states are connected by a 580 nm optical transition. Within each electronic state, the 6 nuclear spin sublevels are split into Kramers doublets, with opposite nuclear spin orientations for the two states in each doublet. In the static magnetic field used in this work, the $b \leftrightarrow \bar{b}$ nuclear spin transition at 141 kHz was probed using precision rf spectroscopy.

 \bar{b} state.

Two rf $\pi/2$ spectroscopy pulses at a carrier frequency f, separated by $T = 400 \,\text{\textmu s}$ and with a relative phase $\phi_{\rm rf}$, are applied to drive the $b \leftrightarrow \bar{b}$ transition. We then apply a second adiabatic sweep over the $b \leftrightarrow a$ transition, which transfers the ions in b to a. Finally, optical probe pulses tuned to $^{7}F_{0}$ a, $\bar{a}\rightarrow{}^{5}D_{0}$ c', \bar{c}' , $\mathcal{D}=\pm1$ are used to measure absorption lines as before, yielding a signal $A(f, \phi_{\rm rf})$ proportional to the population transferred to the b state by the spectroscopy pulses. A timing diagram of the measurement sequence is shown in Fig. [3.](#page-6-0)

To precisely measure the $b-\bar b$ resonance frequency, $f_0(b\bar b),$ we use a modified Ramsey method that yields improved control over systematic errors [\[26](#page-13-0)[–28\]](#page-13-1). In each cycle, we perform measurements for 8 different values of $\phi_{\rm rf}$ between 0 and 2π . The corre- ∞ sponding absorption signal, $A(f,\phi_\text{rf}) \propto \cos\left\{\phi_\text{rf} + 2\pi\left[f - f_0(b\bar{b})\right]T\right\}$ versus ϕ_rf , is fit to

FIG. 3. Pulse sequence for the measurements. The top panel shows the hyperfine levels of the ${}^{7}F_{0}$ and ${}^{5}D_{0}$ states and the transitions driven in each step. Yellow arrows drive optical pumping and absorption probe transitions, blue arrows drive rf transitions between hyperfine states ($a \leftrightarrow b$), and orange arrows drive the $b \leftrightarrow \overline{b}$ transition. The bottom panel shows the optical, rf, and electric field pulses corresponding to the top panel. Colors depicts the frequency detunings from resonance of the pulses used in the transition. The duration of each pulse is listed below the diagram. Each such sequence takes 600 ms.

a sinusoid processed to extract the resonance frequency $f_0(b\bar{b})$ [\[26\]](#page-13-0). The values of $f_0(b\bar{b})$ are separately recorded for the $\mathcal{D} = \pm 1$ ensembles and denoted as $f_0(b\bar{b}, \mathcal{D} = \pm 1)$.

The $b \leftrightarrow \bar{b}$ resonance frequency can be expressed as

$$
f_0(b\bar{b}, \mathcal{D} = \pm 1) = 2Z_b \pm 2W_T \left\langle \vec{I} \cdot \hat{x} \right\rangle, \tag{4}
$$

where Z_b is the Zeeman shift of the b state due to the applied magnetic field, and the P-odd T-odd quantity $\langle \vec{I} \cdot \hat{x} \rangle$ is the expectation value of the nuclear spin projection onto the direction of $\vec{\mathcal{E}}_{\text{eq}}$. Based on the Zeeman and hyperfine structure constants measured in Refs. [\[8,](#page-13-2) [9\]](#page-12-8), we evaluate $|\langle \vec{I} \cdot \hat{x} \rangle| = 0.75$, see Supplemental Material Section II. The time-varying T-violating shift, $\delta W_T \equiv W_T - \text{avg}(W_T)$, and Zeeman shift, Z_b , determined from $f_0(b\bar{b}, \mathcal{D} = \pm 1)$, are shown as a function of measurement time in Fig. [4.](#page-7-0) As the interval between samples of δW_T is non-uniform (due to occasional laser frequency jumps and experiment pauses), we use the Lomb-Scargle periodogram [\[30\]](#page-13-3) to determine its power spectral density.

The periodogram frequencies are sampled uniformly from 313 nHz (half the inverse of the experiment duration, $T_{\text{int}} = 1.59 \times 10^6 \text{ s}$) to 74 mHz (half the inverse of the

FIG. 4. (a) The time-varying T-violating frequency shift δW_T . (b) The Zeeman shift of the b state. Each point in the figure is data from one full experiment cycle. Fluctuations in the Zeeman shift are due to background magnetic field drifts. The Zeeman shift was separated from the ALP signal using the oppositely-polarized ion ensembles as comagnetometers [\[20\]](#page-12-4). The break inserted before the 300 hour mark was used to make a large deliberate change in the magnetic field, in order to test the ability of the comagnetometer comparison to reject magnetic field fluctuations.

experiment cycle time, $T_{\text{cycle}} = 6.7 \text{ s}$ in 603316 steps. The power spectral density of δW_T is shown in Fig. [5.](#page-8-0) To determine the non-ALP background in the δW_T power spectrum, we split the spectrum into 10 log-spaced bins such that the noise power in each bin is approximately frequency-independent. As the ALP field is expected to be coherent with a quality factor of $\sim 10^6$ [\[31\]](#page-13-4), the bandwidth of a possible ALP signal is much smaller than the bin bandwidth for each of the bins. Therefore, we use the average power in each frequency bin to build an exponential distribution to search for significant excess power due to ALP-induced oscillations. A 95% confidence level limit derived from the exponential distribution is shown in Fig. [5.](#page-8-0)

The 95% confidence limits on δW_T oscillations can be used to place a bound on

FIG. 5. Power spectral density of the T-violation frequency shift δW_T . The average of the binned power spectral density (orange, dotted line) and the 95% global confidence level constraint on δW_T oscillation (red, dashed line) are shown.

ALP-gluon coupling using Eq. [3.](#page-3-0) However, we have to consider corrections due to the experiment cycle time and the stochastic nature of the ALP field amplitudes [\[9,](#page-11-1) [32\]](#page-13-5). First, for oscillation frequencies comparable to or greater than $1/T_{\text{cycle}}$, the δW_T oscillation amplitudes would be underestimated due to downsampling in each experiment cycle. We generated sinusoidal data at different frequencies based on the experiment timestamps, accounting for the experiment cycle time, and computed the power spectrum at the measured frequencies. This yields a calibration curve for the experimental sensitivity as a function of oscillation frequency which is used to scale the δW_T exclusion range, similar to the method used in Ref. [\[9\]](#page-11-1). Second, the ALP coherence time is approximately $10⁶$ times the oscillation period, which is comparable to or greater than the measurement time used in this work for frequencies between $1/T_{\text{int}}$ and $1/T_{\text{cycle}}$. Therefore the ALP oscillations must be corrected for a stochastic bias. The ALP field amplitude, a_0 , follows a Rayleigh distribution whose root-mean-square

value is $a_{\text{DM}} = \sqrt{2\rho_{\text{DM}}(\hbar c)^3}/(m_a c^2)$, assuming the ALP is the dominant source contributing to local dark matter with density $\rho_{\rm DM} = 0.4 \ {\rm GeV/cm^3}$ [\[8,](#page-11-0) [33\]](#page-13-6). We increase the deterministic model ALP-gluon coupling bound by a factor of 3 to account for stochasticity following Ref. [\[32\]](#page-13-5). The resulting bound, smoothed with a Savitzky-Golay filter for ease of visualization [\[34\]](#page-13-7), is shown in Fig. [6.](#page-9-0) The value of $\mathscr{S}_{\bar{\theta}}$ that enters Eq. [3](#page-3-0) was calculated to be 3.7 $e \text{ fm}^3$ in Ref. [\[18\]](#page-12-2) and 0.15 $e \text{ fm}^3$ in Ref. [\[19\]](#page-12-3). We use the geometric mean of these two values, 0.74 $e \text{ fm}^3$, to construct the solid line for the exclusion plot shown in Fig. [6,](#page-9-0) and the difference between these values as the uncertainty band. This bound improves the constraints placed by previous atomic [\[10](#page-11-2)[–16\]](#page-12-0) and molecular [\[9\]](#page-11-1) experiments.

FIG. 6. 95% confidence exclusion range on the ALP-gluon coupling from this work. The uncertainty band around the exclusion limit is due to differing theoretical estimates of the nuclear Schiff moment of ¹⁵³Eu [\[18,](#page-12-2) [19\]](#page-12-3). Other laboratory constraints in this range of ALP masses use data from [\[35\]](#page-13-8): nEDM (orange, no stochastic correction applied) [\[7\]](#page-10-5), neutron beam EDM (green, stochasticity corrected) [\[8\]](#page-11-0).

In summary, we have performed precision measurements that constrain oscillatory

symmetry-violation in octupole-deformed nuclei in a crystal, leading to a broadband bound on the parameter space of axionlike dark matter. Higher experimental precision is anticipated in the future, from apparatus upgrades to increase the nuclear spin coherence time and reduce noise in the optical detectors. Our measurements also motivate nuclear structure experiments and calculations to resolve the theoretical uncertainty in $\mathscr{S}_{\bar{\theta}}$ for ¹⁵³Eu.

I. EQUIVALENT ELECTRIC FIELD

 $Eu³⁺$ ions are electrically polarized by their neighboring ions in the YSO crystal. The equivalent electric field, \mathcal{E}_{eq} , interacts with the permanent EDM of Eu³⁺ ions induced by the nuclear Schiff moment to produce the measured T-violating frequency shift W_T , as described in Eq. 3 in the main text.

To date, there have not been any calculations of \mathcal{E}_{eq} in Eu:YSO. The nuclear Schiffmoment-induced energy shift in $EuCl₃: 6H₂O$ was calculated in Ref. [\[1\]](#page-16-0), from which we can estimate \mathcal{E}_{eq} in EuCl₃:6H₂O. The value of \mathcal{E}_{eq} in Eu:YSO is then obtained by scaling the $EuCl₃: 6H₂O$ equivalent electric field using the ratio of the experimentallymeasured Stark shift coefficients of these two systems [\[2,](#page-16-1) [3\]](#page-12-7).

In EuCl₃:6H₂O, the nuclear Schiff moment of 153 Eu shifts the ion energy levels by

$$
\delta E_T = 3 \times 10^{-9} \theta \text{ eV},\tag{S1}
$$

according to Ref. [\[1\]](#page-16-0). This energy shift is based on an estimated nuclear Schiff moment of $S = 5\theta$ e · fm³. The permanent electric dipole moment of the $^{153}Eu^{3+}$ ion induced by the nuclear Schiff moment is [\[4\]](#page-12-5)

$$
d_{Eu} = 0.33 \times 10^{-17} \, \text{e} \cdot \text{cm} \frac{S}{\text{e} \cdot \text{fm}^3} = 1.7 \times 10^{-17} \theta \, \text{e} \cdot \text{cm}.
$$

From Eqs. [S1](#page-14-0) and [S2,](#page-14-1) the equivalent electric field on the $^{153}Eu^{3+}$ ion in EuCl₃:6H₂O is

$$
\left| \mathcal{E}_{\text{eq}}(\text{EuCl}_3 : 6H_2O) \right| = \left| -\frac{\delta E_T}{d_{\text{Eu}}} \right| = 0.18 \,\text{GV cm}^{-1}.
$$
 (S3)

The differential Stark shift coefficient for the ${}^{7}F_0 \rightarrow {}^{5}D_0$ optical transition is

$$
\Delta \zeta \equiv -\frac{\delta (E(^5D_0) - (E(^7F_0))}{\delta \mathcal{E}} = \Delta \alpha L \, \mathcal{E}_{\text{eq}}.
$$
 (S4)

where $\Delta\alpha\equiv\alpha(^5D_0)-\alpha(^7F_0)$ is the differential dipole scalar polarizability of the $^7F_0\rightarrow$ ⁵D₀ transition, and $L = (\epsilon_r + 2)/3$ is a local field correction factor with ϵ_r being the relative permittivity of the crystal [\[5\]](#page-16-2).

The relative permittivity is $\epsilon_r \approx 3.6$ in EuCl₃ : 6H₂O [\[5\]](#page-16-2) compared to $\epsilon_r = 9.36$ along

TABLE S1. Projections of the nuclear spin along the crystal D1 (\hat{x}) , D2 (\hat{y}) , and b (\hat{z}) axes.

	$ \langle \vec{I} \cdot \hat{x} \rangle \,\, \langle \vec{I} \cdot \hat{y} \rangle \,\, \langle \vec{I} \cdot \hat{z} \rangle$		
$ \bar{a}\rangle$		-1.48 -0.96 1.72	
	$ a\rangle$ 1.48 0.96 -1.72		
$ b\rangle$	-0.75	-0.03	0.91
$ b\rangle $	0.75		$0.03 - 0.91$
$ \bar c\rangle$	-0.05	$0.20\quad 0.33$	
	$ c\rangle $ 0.05	-0.20	-0.33

the crystal D1 axis in Eu:YSO [\[6\]](#page-16-3). The measured Stark shift coefficients are $\Delta \zeta =$ $1.57(2)$ kHz/(V/cm) in EuCl₃:6H₂O [\[2\]](#page-16-1), and $\Delta \zeta = 27.2(2)$ kHz/(V/cm) along the D1 axis in Eu:YSO. Therefore we estimate the component of $\vec{\mathcal{E}}_{\mathrm{eq}}$ along the D1 axis in Eu:YSO to be

$$
|\vec{\mathcal{E}}_{\text{eq}}(\text{Eu} : \text{YSO}) \cdot \hat{x}| = |\mathcal{E}_{\text{eq}}(\text{EuCl}_3 : 6H_2\text{O})| \left| \frac{\Delta \zeta(\text{Eu} : \text{YSO})}{\Delta \zeta(\text{EuCl}_3 : 6H_2\text{O})} \right| \frac{L(\text{EuCl}_3 : 6H_2\text{O})}{L(\text{Eu} : \text{YSO})} = 1.5 \,\text{GV} \,\text{cm}^{-1}.
$$
\n
$$
(S5)
$$

II. NUCLEAR SPIN PROJECTIONS

In this section we evaluate the Eu^{3+} nuclear spin projection along the crystal D1 axis, $\langle \vec{I} \cdot \hat{x} \rangle$, which is used in Eq. 4 of the main text. The hyperfine and Zeeman Hamiltonian for the nuclear spin degree of freedom in the ground ${}^{7}F_{0}$ electronic state in Eu:YSO is

$$
\mathcal{H} = \vec{I} \cdot \mathbf{Q} \cdot \vec{I} + \vec{B} \cdot \mathbf{M} \cdot \vec{I},\tag{S6}
$$

where $\vec{B} \approx 225 \text{ G} \cdot \hat{x}$ is the magnetic field, Q is the quadrupole tensor, and M is the gy-romagnetic tensor [\[7\]](#page-16-4). The quadrupole tensor Q for the ground ${}^{7}F_{0}$ electronic state of ¹⁵³Eu:YSO is reported in Ref. [\[8\]](#page-13-2). The gyromagnetic tensor M has only been measured for the ${}^{7}F_0$ state of ${}^{151}Eu$ ($I = 5/2$) in YSO [\[9\]](#page-12-8). We scale the ${}^{151}Eu$:YSO M tensor by the ratio of the nuclear magnetic dipole moments of 153 Eu and 151 Eu [\[10\]](#page-16-5), to estimate the M tensor for ¹⁵³Eu:YSO. The nuclear spin eigenstates are obtained from diagonalization of the above Hamiltonian. The projections of the nuclear spins along the D1, D2, and b dielectric axes of the crystal are shown in Table [S1.](#page-15-0)
