Moiré lattices created in two-dimensional heterostructures exhibit rich many-body physics of interacting electrons and excitons and, at the same time, suggest promising optoelectronic applications. Here, we study the cooperative radiance of moiré excitons that is demonstrated to emerge from the deep subwavelength nature of the moiré lattice and the strong excitonic onsite interaction. In particular, we show that the static dipole-dipole interaction between interlayer excitons can strongly affect their cooperative optical properties, suppressing superradiance of disordered states while enhancing superradiance of ordered phases of moiré excitons. Moreover, we show that doping permits direct control of optical cooperativity, e.g., by generating supperradiant dynamics of otherwise subradiant states of excitons. Our results show that interlayer moiré excitons offer a unique platform for exploring cooperative optical phenomena in strongly interacting many-body systems, thus, holding promise for applications in quantum nonlinear optics.

Two-dimensional semiconductors such as atomically thin transition-metal dichalcogenides (TMDCs) and their moiré heterostructures have recently emerged as a platform to realize strongly correlated electronic phases [\[1–](#page-4-1)[8\]](#page-5-0). Light-matter interaction in semiconducting TMDC hetrostructures results in tightly bound optical excitations - excitons - which have played a crucial role in unveiling elusive correlated electronic phases [\[9](#page-5-1)[–12\]](#page-5-2). Moreover, the possibility to couple photons and moiré superlattices has ushered in broad explorations of photonic and optoelectronic phenomena and applications [\[13–](#page-5-3)[20\]](#page-5-4).

However, their optical properties beyond the physics of local light-matter coupling has remained relatively unexplored. While most studies have focused on electrostatic interactions between moiré excitons [\[21](#page-5-5)[–23\]](#page-5-6), their mutual coupling via the electromagnetic vacuum can result in collective optical effects [\[24–](#page-5-7)[31\]](#page-5-8) that are particularly pronounced in the deep subwavelength limit of typical moiré lattice spacings.

In this article, we describe how the combination of such collective light-matter coupling and strong excitonexciton interactions gives rise to quantum many-body dynamics and cooperative optics – and most prominently superradiant photon emission [\[32](#page-5-9)[–34\]](#page-6-0). More generally, the interplay of strong onsite repulsion, electrostatic dipolar interactions, long-range light-induced excitation hopping, and long-range dissipation suggests moiré excitons as an interesting open many-body system. Here, we explore this interplay and its effect on cooperative superradiant emission processes. We reveal pronounced effects of static dipole interactions and show that it suppresses the otherwise strong superradiance of fully excited lattices, while it can generate superradiance by ordered arrays of partially filled lattices that may form due to dipolar repulsion between excitons [\[35\]](#page-6-1). Electron doping is also found to have remarkably strong effects on cooperative decay, whereby the formation of generalized

FIG. 1. (a) Illustration of a moiré potential in layered TMDC heterostructures. Interlayer excitons have strong dipolar interactions V_{ij} and undergo long-range photon-mediated hopping with amplitudes J_{ij} unless the site is already occupied by an exciton. Their collective decay is described by distancedependent rates γ_{ij} according to Eqs.[\(2\)](#page-1-0)-[\(4\)](#page-2-0), with $\gamma_{ii} = \gamma$, shown in panel(b). (c) Distance dependence of J_{ij} and V_{ij} for a relative dipolar interaction strength of $\varepsilon_{dd} = 5$ [cf. Eq.[\(5\)](#page-2-1)].

Wigner crystals of electrons is shown to induce superradiant emission bursts from otherwise slowly decaying lattices of excitons. Our findings highlight the role of static particle interactions in controlling cooperative radiance, and contribute to understanding the optical properties of moiré quantum materials as well as their use to probe many-body phenomena of interacting excitons and electrons.

We consider interlayer excitons formed by an electronhole pair that are located in separate layers of a twodimensional heterostructure, realized by two stacked TMDC monolayers (e.g. WS_2/WSe_2) as sketched in Fig. $1(a)$ [\[14,](#page-5-10) [36\]](#page-6-2). A small lattice mismatch or a finite twist angle between the monolayers generates a slowly varying moiré pattern of the potential for electrons and holes [\[37,](#page-6-3) [38\]](#page-6-4). As the excitons localize in the minima of this potential they form an array with a moiré lattice constant $a \sim 10$ nm [\[35\]](#page-6-1), which is orders of magnitude larger than that of the underlying atomic crystal but lies well below the optical wavelength λ of the excitonic transition. As a result, such moiré lattices constitute a subwavelength array in which exciton-photon interactions can be highly collective, whereby emitted photons can be reabsorbed at other lattice sites. This vacuummediated, photon-exchange generates a long-range coupling between distant moiré sites and results in collective photon emission associated with the formation of superand subradiant states. The deep subwavelength nature of the system, $a \ll \lambda$, results in a collective coupling which can be orders of magnitude larger than the singlesite emission rate and is expected to further enhance such collective effects, e.g., compared to neutral atoms in op-tical lattices [\[34,](#page-6-0) [39](#page-6-5)[–54\]](#page-6-6), where typically $a \leq \lambda$.

However, strong exciton-exciton interactions are required to create conditions for cooperative optical phenomena beyond the linear physics of collectively coupled classical dipoles. Recently, it was observed that forcing two excitons to occupy the same moiré site gives rise to a large Coulomb repulsion energy that results in an excitonic Mott insulator [\[21–](#page-5-5)[23,](#page-5-6) [35\]](#page-6-1), with a single exciton per moiré site. This exclusion of double occupation permits treating interlayer excitons as spin-1/2 degrees of freedom, whereby the raising and lowering operators $\hat{\sigma}_i^+$ and $\hat{\sigma}_i^-$ describe the creation and recombination of an exciton at the i^{th} site of the moiré lattice. Moreover, the electron-hole separation of the interlayer excitons in different layers implies a sizable static, out-of-plane electric dipole moment, d , that is controlled by the distance between the two layers [\[55,](#page-6-7) [56\]](#page-6-8). For a dipole orientation orthogonal to the 2D layer, this lead to isotropic longrange interactions

$$
V(\mathbf{r}_i, \mathbf{r}_j) = \frac{d^2}{4\pi\varepsilon_0\varepsilon_r |\mathbf{r}_i - \mathbf{r}_j|^3}
$$
(1)

between excitons in different $(i \neq j)$ moiré sites with positions \mathbf{r}_i and \mathbf{r}_j . Here, ε_r is the relative permittivity that accounts for the polarization in the material for a given host medium such as hBN.

In addition to these electrostatic two-body interactions, the oscillating, in-plane dipole of excitons, responsible for photon emission, can couple through vacuummediated interactions. The resulting interplay of these competing two-body process makes dipolar moiré excitons a unique platform to explore strong-interaction effects on cooperative radiance of effective two-level quantum emitters.

The resulting unitary dynamics is determined by the Hamiltonian

$$
\hat{H} = t \sum_{\langle i,j \rangle}^{N} \hat{\sigma}_i^+ \hat{\sigma}_j^- + \sum_{i \neq j}^{N} \left(-\hbar J_{ij} \hat{\sigma}_i^+ \hat{\sigma}_j^- + \frac{V_{ij}}{2} \hat{n}_i \hat{n}_j \right) , \tag{2}
$$

FIG. 2. (a) The time-dependent cooperative emmission rate Γ demonstrates strong suppression of superradiance by static dipole-dipole interactions, quantified by the dimensionless interaction strength ε_{dd} . The spectrum of collective decay rates is shown in panels (b) and (c) for a 3×3 triangular lattice $(N = 9)$ with $a/\lambda = 0.05$ and for different numbers $N_{\rm x}$ of excitons in the lattice. States to the right of the dashed line are superradiant, while those to the left are subradiant. The color code shows their the time-integrated population P_{α} during the cooperative decay of an initially fully excited lattice (N_{x}) , and the solid lines show the time-evolving decay rates of panel (a). The gray dashed lines correspond to independent photon emission as $N_x = N \exp(-\gamma t)$.

where $\hat{n}_i = \hat{\sigma}_i^+ \hat{\sigma}_i^-$ gives the exciton occupation at site i and N denotes the number of lattice sites. The two-body terms $J_{ij} = J(\mathbf{r}_i - \mathbf{r}_j)$ and $V_{ij} = V(|\mathbf{r}_i - \mathbf{r}_j|)$ describe the photon-mediated hopping of excitons and their static dipole-dipole interaction. The tunneling of excitons between neighbouring sites with an amplitude t adds to the photon-induced exchange processes. While t , which is determined by Wannier overlap of excitons located at neighboring moiré sites, decays exponentially with the lattice constant [\[57\]](#page-6-9), $J(a)$ only decreases algebraically as $J(a) \sim (\lambda/a)^3$, such that the value of a controls the relative contribution from each process. For simplicity, we focus here on conditions where direct exciton tunneling plays a minor role, but an extension to finite values of t is straightforward without further complications. Finally, one can incorporate radiative recombination of the excitons based on the Lindbladian master equation [\[24\]](#page-5-7)

$$
\partial_t \hat{\rho} = i\hbar^{-1} \left[\hat{\rho}, \hat{H} \right] + \sum_{ij} \gamma_{ij} \left(\hat{\sigma}_j^- \hat{\rho} \hat{\sigma}_i^+ - \frac{1}{2} \left\{ \hat{\sigma}_i^+ \hat{\sigma}_j^- , \hat{\rho} \right\} \right)
$$
\n(3)

for the many-body density matrix $\hat{\rho}$ of the system. Here, the two-body decay terms γ_{ij} account for the collective photon emission by the exciton array, whereby the diagonal element $\gamma_{ii} = \gamma$ corresponds to the bare one-body emission rate due to recombination of a single localized

FIG. 3. (a) Relative enhancement or suppression of the superradiant peak [cf. Eq.[\(8\)](#page-3-0)] due to static dipole-dipole interactions for two interaction strengths ε_{dd} and different initial filling fractions f_x . The solid lines show results for random initial configurations. The orange crosses show the enhancement for $\varepsilon_{dd} = 5$ and ordered configurations at filling fractions $f_x =$ $1/4$, $1/3$, $1/2$, $2/3$, shown in panels (c)-(f) along with the decay dynamics of these ordered states for $\varepsilon_{dd} = 0$ (black line), $\varepsilon_{dd} = 1$ (blue line), and $\varepsilon_{dd} = 5$ (orange line). Panel (b) shows the dependence of the superradiant-peak maximum as a function of f_x and $\varepsilon_{\rm dd}$ for random initial configurations.

exciton at a given moiré site i. The corresponding decay rates along with the photon-mediated exchange amplitude are determined as [\[24\]](#page-5-7)

$$
J_{ij} - i\frac{\gamma_{ij}}{2} = -\frac{3\pi\gamma}{\omega}\bar{\mathbf{p}}^{\dagger}\mathbf{G}(\mathbf{r}_{i} - \mathbf{r}_{j})\bar{\mathbf{p}},
$$
(4)

by the dyadic Green's tensor G of the electromagnetic field [\[58\]](#page-6-10), the exciton resonance frequency $\omega = c/(\sqrt{\varepsilon_r}\lambda)$ and the unit vector $\bar{\mathbf{p}} = \mathbf{p}/p$ of the transition dipole moment p. Since the optical transition in TMDC bilayer structures is valley-selective, only a single circular polarization is relevant for a valley polarized initial state of the excitons. Figure $1(b),(c)$ shows the dependence of γ_{ij} , J_{ij} , and V_{ij} on the distance between excitons and illustrates the long-range of the photon mediated coupling that typically covers a large number of moiré sites for $a \ll \lambda$.

For characteristic layer distances of $1 - 2 \text{ nm}$ [\[56\]](#page-6-8) and moiré lattice constants in the range of $a \sim 10 \text{ nm}$, the dipole interaction between nearest lattice sites can take on values of $V(a) = 0.1 \,\text{meV} - 1 \,\text{meV}$. With typical transition energies of $\hbar\omega \sim 1$ eV, lattice spacings are in the deep subwavelength regime of $a/\lambda \sim 10^{-2}$ to $a/\lambda \sim 10^{-1}$. Radiative lifetimes of moiré excitons where found to be as short as $\gamma^{-1} \sim 1$ ns and as long as $\gamma^{-1} \sim$ 100ns [\[36,](#page-6-2) [59\]](#page-6-11), which determines the strength $J(r)$ of the photon-mediated exciton hopping. At small distances $r \ll \lambda$, it features a dipolar scaling $J(\mathbf{r}) = 3\gamma/8(kr)^3$

(cf. Eq[.4\)](#page-2-0), and we can use the parameter

$$
\varepsilon_{\rm dd} = \frac{V(a)}{\hbar J(a)} = \frac{d^2}{4\pi\varepsilon_0} \frac{\sqrt{\varepsilon_r}(\omega/c)^3}{\hbar \gamma} = \frac{2d^2}{p^2},\qquad(5)
$$

to quantify the strength of static dipole-dipole interactions relative to the dipolar exchange of excitons. The above numbers suggest values as large as $\varepsilon_{dd} \sim 10$, indicating strong interaction effects.

In order to obtain an intuitive picture of the resulting cooperative decay dynamics, we first consider a small triangular lattice with a spacing of $a = \lambda/20$ in the absence of static dipole-dipole interactions. For the chosen parameters and small system size, the decay rates, $\gamma_{ii} \approx \gamma_{ii} = \gamma$ are nearly homogeneous across the lattice. Such a system displays Dicke superradiance above half filling [\[32,](#page-5-9) [33\]](#page-6-12), whereby a short light pulse with a rising intensity is emitted spontaneously, as opposed to the exponentially decaying fluorescence signal from independent excitons. This superradiant burst results from the synchronized decay of multiple excitons due to stimulated emission processes [\[32,](#page-5-9) [33\]](#page-6-12). One can analyze this process using the effective non-Hermitian Hamiltonian

$$
\hat{\mathcal{H}} = -i \sum_{i,j} \gamma_{ij} \hat{\sigma}_i^+ \hat{\sigma}_j^- \tag{6}
$$

that follows from Eq.[\(3\)](#page-1-1) and its eigenvalues $\tilde{\Gamma}_{\alpha}$ yield the collective decay rates of the system. We can diagonalize Eq. (6) for a small number N of lattice sites in a given subspace of N_x excitons. The resulting spectrum of collective decay rates is shown in Fig[.2\(](#page-1-2)b) and (c). In addition, we simulate the cooperative decay dynamics of an initially unit filled lattice and determine the time integrated population P_{α} of the collective eigenstates with decay rates $\tilde{\Gamma}_{\alpha}$. For noninteracting excitons [Fig[.2\(](#page-1-2)b)], $\varepsilon_{dd} = 0$, one observes expectedly that the system predominantly evolves along the most superradiant states as it decays with a rapid burst of emitted photons.

However, as $Fig.2(c)$ $Fig.2(c)$ $Fig.2(c)$ illustrates, this typical superradiant decay behavior can be altered significantly by the dipole-dipole interaction V_{ij} between excitons. While it merely shifts the energy of exciton pair states, the static interaction generates a strong coupling in the basis of the collective eigenstates of Eq[.6.](#page-2-2) As a result, it transfers population out of the most superradiant states towards lower decay rates and thereby suppresses superradiance during photon emission. The effect can also be understood by noting that the most superradiant eigenstate of Eq[.6,](#page-2-2) from which all excitons emit in synchrony, is the most symmetric superposition state of delocalized excitons. The dipole-dipole interaction breaks this symmetry for any lattice filling $N_{x}/N < 1$ such that exciton-exciton correlations generated by V_{ij} simultaneously suppress superradiance.

In order to analyse this effect for larger lattices, we use a third-order cumulant expansion [\[60,](#page-6-13) [61\]](#page-6-14), which was previously found to yield a reliable description of superradiant decay dynamics in noninteracting ($\varepsilon_{dd} = 0$) systems [\[62](#page-6-15)[–64\]](#page-6-16). The total rate of photon emission is obtained from

$$
\Gamma(t) = -\frac{1}{N_{\rm x}} \frac{d}{dt} \sum_{i} \langle \hat{n}_{i} \rangle = \frac{1}{N_{\rm x}} \sum_{i,j} \Gamma_{ij} \langle \hat{\sigma}_{i}^{+} \hat{\sigma}_{j}^{-} \rangle. \tag{7}
$$

Starting from a state with no spatial coherence, $\langle \hat{\sigma}_i^+ \hat{\sigma}_j^- \rangle = \delta_{ij} \langle \hat{n}_i \rangle$, the initial fluorescence signal simply arises from the independent photon emission of each exciton with a rate $\Gamma(0) = \gamma$ that is given by the sum of the one-body decay rates $\gamma = \Gamma_{ii}$ over all $N_{\rm x} = \sum_i \langle \hat{n}_i \rangle$ initially prepared excitons. As the system evolves, the rate changes, leading to either subradiant $(\Gamma \langle \gamma \rangle)$ or superradiant $(\Gamma > \gamma)$ decay. In order to quantify the effects of the static dipole-dipole interactions, we record the maximum emission rate Γ_{max} during the decay dynamics and calculate the relative enhancement or suppression

$$
\eta = \frac{\Gamma_{\text{max}}(\varepsilon_{\text{dd}})}{\Gamma_{\text{max}}(\varepsilon_{\text{dd}} = 0)}
$$
(8)

of this maximum rate compared to the non-interacting case, $\varepsilon_{dd} = 0$. In Fig[.3](#page-2-3) we show this ratio as a function of the initial exciton density, $f_x = N_x(t = 0)/N$, for a randomly filled lattice. In the absence of interactions superradiance sets in for initial filling fractions of $f_{\rm x} \geq 1/2$, and we indeed find a reduction of the maximum rate by dipole-dipole interactions above this value.

FIG. 4. (a) Cooperative decay dynamics of an ordered initial state at $f_x = 1/3$ without interactions ($\varepsilon_{dd} = 0$) for no electron doping $(f_e = 0,$ blue curve) and finite electron doping $(f_e = 2/3, \text{ orange curve})$. Doping with $f_e = 1 - f_x$ can generate superradiance. (b) The interplay of electron doping (f_e) and excitonic dipole-dipole interactions (ε_{dd}) can, however, also suppress coopreative decay (see text for details) The initial exciton filling is $f_x = 1 - f_e$ in (b).

The suppression of the superradiant burst increases not only with the strength ε_{dd} of the dipole-dipole interaction but also with the initial exciton density $f_{\mathbf{x}}$. The absolute effect on superradiance is quantified in Fig. [3\(](#page-2-3)b), which shows the maximum emission rate as a function of ε_{dd} and $f_{\rm x}$. The superradiant burst is strongly diminished by the dipole-dipole interaction and eventually vanishes with increasing interaction strength, even at the maximum initial exciton density of $f_x = 1$.

Remarkably, the described effect on collective radiance can be reversed for ordered initial states, which may be prepared as low-energy states of the interacting dipolar excitons at sufficiently low temperatures. Different examples that occur at specific commensurate lattice fill-ings are shown in Fig[.3.](#page-2-3) For initial densities $f_x \leq 1/2$, the noninteracting decay dynamics is subradiant and predominantly populates collective eigenstates of Eq.[\(6\)](#page-2-2) with $\tilde{\Gamma}_{\alpha} < \gamma$ during the decay of the ordered initial exciton configuration. Consequently, the coupling between the collective eigenstates that is induced by the dipoledipole interaction can, in this case, transfer population to states with larger decay rates. As demonstrated in Fig[.3\(](#page-2-3)c)-(e) for different ordered configurations, this coupling is indeed strong enough to not only suppress the subradiant nature of the decay dynamics, but to generate a significant superradiant burst under conditions that would otherwise yield a slow decay of the exciton lattice.

The found enhancement of cooperative decay is, however, not limited to low-density initial states $(f_0 \leq 1/2)$ that do not show superradiance in the absence of interactions. This is demonstrated in Fig[.3\(](#page-2-3)f) for an ordered initial state with $f_x = 2/3$, where the superradiant burst that already occurs for noninteracting emitters is steadily enhanced upon increasing the static dipole moment of the excitons.

In contrast to atomic systems, it is not straightforward

to compare the collective decay dynamics to the one-body decay of isolated emitters, as excitons are typically generated as collective excitations in the semiconducting material. However, exploiting the moiré lattice structure this may be possible by electron doping. Electrically injected charge carriers also localize in the minima of the periodic moiré potential. Moreover, due to their strong repulsion, electrons form an insulating phase at unit filling and have been found to arrange in generalized Wigner crystals (GWCs) for lower commensurate electron filling fractions f_e [\[1\]](#page-4-1). In WS_2/WSe_2 heterostructures, it was observed that the generation of an exciton at the same site as a doped charge carrier costs a large energy and is avoided below a total filling $f_{\text{tot}} = f_{\text{e}} + f_{\text{x}} = 1$ [\[21,](#page-5-5) [23,](#page-5-6) [65\]](#page-6-17). Thus, electrons and excitons occupy complementary moiré sites below $f_{\text{tot}} < 1$ and reconfigurable excitonic crystals are expected when electrons form GWCs. Generating excitons in a doped material just below unit electron filling, would quench collective interactions and thus allow preparation of localized and isolated excitons that individually undergo exponential decay and independently emit photons. Strong electron doping in moiré lattices thus offers a way to turn off cooperative radiance and measure the one-body emission rate γ .

More surprisingly, one finds that electron doping can also generate a superradiant burst. In order to see this, let us consider an ordered initial state of the excitons with a filling fraction $f_x = 1/3$, as depicted in the lower inset of Fig[.4\(](#page-3-1)a). As discussed above, such a filling fraction will undergo slow subradiant decay [see Fig[.4\(](#page-3-1)a)] since the initial exciton density is well below $f_{\rm x} < 1/2$. The decay dynamics changes dramatically when doping the system with $f_e = 2/3$ such that electrons form a GWC as illustrated in the upper inset of Fig[.4\(](#page-3-1)a). While this does neither affect the initial density, f_x , nor the spatial configuration of the excitons, it generates a significant superradiant burst. The effects of doping on the decay dynamics are summarized in Fig[.4\(](#page-3-1)b), where we show the ratio

$$
\chi = \frac{\Gamma_{\text{max}}(f_e = 1 - f_x)}{\Gamma_{\text{max}}(f_e = 0)}
$$
\n(9)

of the maximum emission rate Γ_{max} of a maximally doped lattice and without electron doping. For vanishing dipole-dipole interactions ($\varepsilon_{dd} = 0$) electron doping with $f_e = 1 - f_x$ consistently increases the superradiant decay rate of the system. Compared to the undoped system, the immobile electrons of the formed Wigner crystal persistently block all unoccupied lattice sites, which effectively increases the excitonic filling fraction of the remaining moiré sites to unity and, thereby, generates a superradiant burst. Increasing the strength of the dipole-dipole interaction diminishes this doping-induced enhancement of cooperative decay since it efficiently suppresses superradiance of unit-filled lattices, as discussed above [cf. Fig[.3\(](#page-2-3)a)]. Interestingly, the effect of doping can even reverse for strong exciton interactions and $f_{\rm x}$, where the static dipole-dipole interactions tend to gener-ate superradiance in the undoped case [cf. Fig[.3\(](#page-2-3)c)-(e)] but strongly suppress superradiance for maximal doping where the effective exciton density is increased to unity. This therefore nicely illustrates that electron doping can induce superradiance even at relatively small exciton filling fractions and modify the emission properties of the system.

In conclusion, the results of this work suggest moiré quantum materials as a promising platform to study many-body cooperative optics of strongly interacting quantum emitters. While we have focused here on cooperative decay, exploring the driven dissipative many-body dynamics and emerging non-equilibrium steady states would present an interesting extension. Here, the doping with electrons at filling fractions away from the Wigner crystalline phases considered in this work is appealing for studying driven-dissipative phases of strongly interacting moiré electrons and optically pumped moiré excitons [\[66\]](#page-6-18). Moreover, the inclusion of spin-valley degrees of freedom [\[67\]](#page-7-0) would permit optical probing of quantum magnetism in a driven-dissipative setting, whereby the possibility of initializing exciton spins could allow for optical control of electronic spin order [\[68\]](#page-7-1). Given the expectedly correlated nature of the excitonic states that form dynamically during their cooperative decay, understanding the nonclassical statistics and emerging photon correlations in the emitted light present another important question for future work. Effects of static particle interactions on cooperative optical processes, as studied in this work, may also become relevant in optical-lattice experiments [\[41,](#page-6-19) [44,](#page-6-20) [69,](#page-7-2) [70\]](#page-7-3) with magnetic atoms [\[71,](#page-7-4) [72\]](#page-7-5).
