Cononsolvency occurs when two miscible, competing good solvents for a polymer are mixed, resulting in a loss of solubility. In this study, we demonstrate through simulations, supported by theory, that cononsolvency can be driven solely by solvent-cosolvent attraction (ϵ_{sc}). The primary mechanism underlying this behavior is the emergent depletion effect, which is amplified by solvent-cosolvent interactions. The polymer reaches a compact state when the solvent and cosolvent fractions are equal ($x_s = x_c = 0.5$), a finding that aligns with predictions from Flory-Huggins theory and the random phase approximation. We show that this cononsolvency behavior is observed for different cosolvent sizes, provided the cosolvent density remains below the depletion threshold and the sizes of solvent and cosolvent particles are not smaller than the monomer size. Additionally, we investigate the role of temperature and find that cononsolvency weakens as temperature increases, due to a reduction in the depletion effect. Finally, we show that when preferential cosolvent attraction is introduced in this simple model, it leads to cononsolvency driven by bridging interactions, occurring at lower cosolvent fractions ($x_c < 0.5$).

I. INTRODUCTION

The coil-to-globule transition in polymers can occur through various pathways, depending on the specific conditions and interactions at play. Common pathways include changes in solvent quality, the application of external pressure, and the addition of salts or other cosolutes, all of which can trigger conformational changes in polymers. Solvent quality is a particularly crucial factor, as modifications in the nature of the solvent can drive the coil-to-globule transition. In poor solvents, where polymer-solvent interactions are weaker, polymers tend to collapse, a transition often induced by increasing the fraction of non-solvents or altering solvent properties [1–3]. Another pathway involves applying external pressure to reduce the available volume for the polymer chain, leading to collapse. Although less common than temperature-induced transitions, pressure-induced transitions are studied under specialized conditions [4, 5].

In addition, the presence of salts or cosolutes can influence the coil-to-globule transition by modifying the ionic strength of the solution or introducing specific interactions between polymer and solute particles. This is especially relevant in the study of biopolymers like proteins and DNA, which can undergo conformational changes in response to environmental factors such as pH, ionic strength, or the presence of ligands and cofactors [6–8]. In biopolymers, hydrophobic collapse is a crucial mechanism, where hydrophobic residues aggregate to minimize contact with water, leading to the formation of compact,

globular structures, such as in protein folding [9, 10]. Additionally, charged polymers can experience coil-toglobule transitions in response to changes in electrostatic interactions, driven by alterations in the solution's ionic strength and additional salt concentration [6, 11, 12]. An interesting environment for studying these transitions is the interior of living cells, which are highly crowded with macromolecules and small cosolutes. In such crowded conditions, depletion interactions can play a significant role in inducing coil-to-globule transitions. Depletion occurs when smaller particles or colloids act as depletants, leading to the collapse of polymer chains into a more compact, globular conformation [13–15]. This phenomenon, driven by the excluded volume effect, has practical applications in colloid and polymer science, including the food industry. Such a phenomenon has also be used to explain the biomolecular collapse-unfolding transitions in biomolecules inside the crowded living cell. Specific interactions between polymers and solvent/crowder particles, can also lead to unexpected coil-to-globule transitions, particularly when attractive crowders are involved, as demonstrated in several recent studies [16–28].

In our recent work [27], we showed that neutral polymers with very weak self-interactions, when exposed to weakly attractive crowders, undergo a distinct coil-to-globule transition as the crowder-crowder attraction increases, depending on crowder density. Building on this observation, we investigate the phenomenon of cononsolvency driven by solvent-cosolvent attraction. Cononsolvency is a fascinating and complex phenomenon, particularly relevant in mixed solvent systems [29–34]. It occurs when a polymer, soluble in both components of a binary solvent mixture, becomes insoluble when the solvents are mixed in specific proportions. This counterintuitive behavior contrasts with the expected intermediate solubility between the two pure solvents. The underly-

^{*} hiteshgarg@imsc.res.in

[†] divyanayar@mse.iitd.ac.in

[‡] vani@imsc.res.in

ing mechanism of cononsolvency is driven by intricate interactions among the polymer, solvent, and cosolvent particles, influenced by factors such as the polymer's hydrophilicity or hydrophobicity, solvent polarity, and thermodynamic conditions like temperature and pressure. Several theories have been proposed to explain cononsolvency, with a central focus on the balance between polymer-solvent and solvent-(co)solvent interactions. In some cases, the addition of a cosolvent disrupts favorable polymer-solvent interactions, resulting in decreased solubility. Another significant factor is the change in solvent quality as the composition varies: a cosolvent may alter the solvation environment around the polymer, potentially leading to phase separation. Moreover, entropic contributions from polymer-solvent interactions, along with associated free energy changes in the solvent mixture, play pivotal roles in driving the cononsolvency effect. This phenomenon has been extensively investigated in systems such as water-alcohol mixtures with polymers like poly(N-isopropylacrylamide) (PNIPAM) [20, 31, 35].

In this study, we demonstrate that the coil-globulecoil transition can be induced using a minimalistic model where all interactions, except those between solvent and cosolvent particles, are repulsive. Contrary to conventional theories emphasizing preferential interactions between the polymer and one of the solvents, our model assumes symmetric interactions between the polymer and both solvent types. Yet, coil-to-globule transitions are observed solely by tuning solvent-cosolvent interactions. This outcome is attributed to the emergence of effective depletion interactions in the system. Additionally, we show that the strength of these depletion interactions, modulated by solvent-solvent attraction, enhances polymer collapse. Finally, we explore how differential interactions between solvent and cosolvent contribute to coil-toglobule transitions in systems influenced by both depletion and bridging interactions. Furthermore, we investigate how size asymmetry between the two solvents and temperature modulate the cononsolvency phenomenon.

II. MODEL AND METHODS

We consider a coarse-grained bead-spring model for a linear homopolymer consisting of N_p identical monomers $(N_p=100)$ in a simulation box $(L=16.5\sigma_p,$ where σ_p is the size of monomer) of volume V, in the presence of a mixture of solvent (N_s) and cosolvent (N_c) particles. The total number of solvent and cosolvent particles, N_{sc} (where $N_{sc}=N_s+N_c$), is set to 4000 and the total solvent number density is defined as $\phi_{sc}=\frac{N_{sc}}{V}$. For all simulations, regardless of the solvent/cosolvent size, the total density ϕ_{sc} is kept constant at 0.890. We varied the cosolvent fraction x_c from 0.1 to 1.0. Unless otherwise stated, the monomers in the polymer, as well as the solvent and cosolvent particles, have the same size.

The adjacent monomers in the polymer are connected by harmonic springs. A pair of non-bonded particles at a distance r interact through the Weeks-Chandler-Andersen (WCA) potential:

$$V_{LJ}(r) = 4\epsilon_{ij} \left[\left(\frac{\sigma_{ij}}{r} \right)^{12} - \left(\frac{\sigma_{ij}}{r} \right)^{6} \right], r < r_c$$
 (1)

where i,j take on values of p, s, and c, depending on whether the particle is a monomer, solvent, or cosolvent. The interactions between intra-polymer monomers and polymer-solvent/cosolvent particles are modeled using the repulsive WCA potential, with $r_c = 1.12\sigma_p$ and $\epsilon_{pp} = \epsilon_{ss} = \epsilon_{cc} = 1.0$, unless otherwise stated. The interaction between solvent and cosolvent particles is taken to be attractive, with $r_c = 3.0\sigma_{sc}$ and the strength of interaction ϵ_{sc} is varied. The monomers of the polymer are connected via harmonic springs

$$V_{bond}(r) = \frac{1}{2}k(r-b)^2,$$
 (2)

where we set $b=1.12\sigma_p,\ r$ the separation between the bonded particles, and k is the stiffness constant. We choose $k=\frac{500\epsilon_{pp}}{\sigma_p^2}$.

The equations of motion were integrated using the

MD LAMMPS software package [36], and visualization of images and trajectories was performed using the Visual Molecular Dynamics (VMD) package [37]. The time step is $\delta t = 0.001\tau$, where $\tau = \sigma_p \sqrt{\frac{m}{\epsilon_{pp}}}$, with m, σ_p , and ϵ_{pp} representing the units of mass, length, and energy scales, respectively. Simulations were run for 2×10^7 steps using the velocity-Verlet algorithm. All simulations were conducted under constant volume and temperature conditions using the Nose-Hoover thermostat, with temperature adjusted as required. The initial configuration was equilibrated in the NPT ensemble for 10⁷ time steps to achieve the desired density. A block average over the last n = 900 frames was calculated to determine the average of each parameter in each simulation, with a block length of 100, resulting in $n_b = 9$ blocks. The standard deviation of these blocks from the mean was computed and divided by $\sqrt{n_b}$ to obtain the error.

III. RESULTS

A. Demonstration of cononsolvency

We first demonstrate the effect of cononsolvency by simulating a polymer in a mixture of solvent and cosolvent, varying the cosolvent fraction x_c . As detailed in the Methods section, all interactions in the system are repulsive, except for the attractive interactions between solvent and cosolvent particles. When the polymer is surrounded solely by either solvent or cosolvent particles, it adopts an extended conformation, as expected. This is evident from the R_g values at $x_c = 0$ and $x_c = 1$ in Figure 1 for different solvent-cosolvent attractive strengths ϵ_{sc} . Between these two extremes, as the cosolvent fraction increases, the polymer undergoes a transition from

FIG. 1. Radius of gyration R_g as a function of cosolvent fraction x_c for different solvent-cosolvent attractive interaction energies. The inset indicates the variation of the asphericity parameter with cosolvent fraction.

an extended to a collapsed conformation, reaching its most compact state at $x_c \sim 0.5$, which corresponds to an equal ratio $\phi_c/\phi_s=1$, where ϕ_s and ϕ_c are the volume fractions of solvent and cosolvent particles, respectively. Figure 1(inset) shows the variation of asphericity α of the polymer, along with R_g , as a function of cosolvent fraction x_c for a solvent-cosolvent interaction strength of $\epsilon_{sc} = 1.0$, further confirming this observation. For cosolvent fractions $x_c > 0.5$, the polymer exhibits a reentrant extended conformation. The results in Figure 1 also indicate that cononsolvency is influenced by the strength of the attraction between solvent and cosolvent particles. Specifically, when the relative attraction strength between solvent and cosolvent particles is lower $(\epsilon_{sc} = 0.5)$ than the strength of all other inter-particle interactions ($\epsilon_{ij} = 1.0$, where i and j represent polymer, solvent, and cosolvent particles), the cononsolvency effect is diminished, and the polymer does not reach a fully collapsed state.

We next quantify the distribution of solvent and cosolvent particles around the polymer by measuring the number of particles within a cutoff distance of $1.5\sigma_s$ from any monomer. This analysis, performed as a function of the cosolvent fraction (x_c) , is presented in Figure 2 for the case of $\epsilon_{sc} = 1.0$. At low cosolvent fractions ($x_c = 0.1$ or $x_c = 0.9$), an increase in the number of particles near the polymer is observed, indicating that particles are drawn toward the polymer, increasing the local density. However, as x_c further increases, the attraction between solvent and cosolvent particles strengthens, leading to their depletion from the polymer surface. This depletion reaches a maximum at $x_c \sim 0.5 \ (\phi_c/\phi_s \sim 1)$, coinciding with the most pronounced cononsolvency effect, as shown in Figure 1. Figure S1 further illustrates the individual contributions of solvent and cosolvent particles

FIG. 2. Total number of solvent and cosolvent particles in contact with polymer within $1.5\sigma_s$ of chain backbone when $\epsilon_{sc}=1.0$. Snapshots of polymer (solvent and cosolvent particles colored blue and green respectively) at different cosolvent fraction x_c are also shown.

near the polymer, highlighting the crossover in their numbers at $x_c = 0.5$. These observations strongly suggest that in the present model, cononsolvency in mixed good solvents is driven by effective and enhanced depletion effects. The conformational states of the polymer, along with the surrounding solvent and cosolvent particles at various cosolvent fractions x_c , are also depicted in Figure 2. To further elucidate the interplay between solvent and cosolvent particles near the polymer as a function of x_c , the radial distribution function of both solvent and cosolvent particles around the polymer was computed, as shown in Figure S2. The reduction in peak heights with increasing x_c further corroborates the depletion of solvent and cosolvent particles, not only near the polymer but also at greater distances, strongly supporting the role of depletion effects in good solvent mixtures within this model.

The theoretical explanation for this observation can be drawn from the Flory-Huggins lattice theory, as discussed by Dudowicz et al. [38]. Within this framework, the total Helmholtz free energy density, \tilde{F}_{total} , consists of two main contributions: the entropic term, arising from the combinatorial free energy density, \tilde{F}_{comb} , and the enthalpic term, \tilde{F}_{ϵ} , which accounts for interaction energies. The enthalpic free energy density \tilde{F}_{ϵ} for homopolymer solutions in a mixture of solvent (s) and cosolvent (c) on a lattice can be expressed as:

$$\tilde{F}_{\epsilon} = -\frac{h}{2k_B T} [\epsilon_{pp} \phi_p^2 + \epsilon_{ss} \phi_s^2 + \epsilon_{cc} \phi_c^2 + 2\epsilon_{ps} \phi_p \phi_s + 2\epsilon_{pc} \phi_p \phi_c + 2\epsilon_{cs} \phi_c \phi_s]$$
(3)

where ϕ_p , ϕ_c , and ϕ_s represent the volume fractions of the polymer, cosolvent, and solvent, respectively. Here, h is the coordination number of the lattice, T is the temperature, and $\epsilon_{\alpha\beta}$ represents the interaction energy

FIG. 3. The varitaion of radius of gyration and energetic part of Flory-Huggins free energy with ratio of cosolvent and solvent fraction, $\frac{\phi_c}{\phi_s}$. \tilde{F}_{ϵ} is shifted by 7.0

between neighboring species α and β . By plotting F_{ϵ} and F_{total} as functions of the cosolvent-to-solvent ratio, ϕ_c/ϕ_s , while keeping ϕ_p constant and assuming attractive solvent-cosolvent interactions, a minimum in the free energy emerges when the cosolvent and solvent fractions are equal, $\phi_c/\phi_s = 1$, as shown in Figure S3 (see SI). The location of the minimum in the variation of the enthalpic free energy \tilde{F}_{ϵ} (shifted vertically by a constant value of 7.0) is in very good agreement with the minimum in R_q obtained from our simulations, as shown in Figure 3 for $\phi_c/\phi_s \sim 1$, corresponding to a cosolvent fraction of $x_c \sim 0.5$. Calculations carried out by Zhang et al. [39], using the random phase approximation, also suggest that solvent quality is symmetric around $\phi_c/\phi_s \sim 1$ for an equal-quality binary mixture, consistent with the results discussed earlier. These findings suggest that the cononsolvency behavior, in the present model, are driven by enthalpic contributions, in contrast to pure depletion interactions, which are entropic in origin.

B. Role of solvent-cosolvent particle sizes on cononsolvency

The role of solvent and cosolvent sizes on polymer conformation is critical, as size asymmetry can significantly influence polymer behavior [40–46]. To investigate the effects of size asymmetry between solvent and cosolvent particles on the cononsolvency phenomenon, we consider three cosolvent sizes: $\sigma_c = 0.50$, 1.00, and 2.00, while keeping the solvent particle size, σ_s , and monomer size, σ_p , constant and same. As shown in Figure 4, cosolvent sizes $\sigma_c = 1.0$ and 2.0 exhibit cononsolvency behavior in the presence of solvent-cosolvent attraction, whereas $\sigma_c = 0.5$ results in the polymer remaining in a collapsed state at all cosolvent fractions. The volume density for $\sigma_c = 0.5$ exceeds the depletion threshold —leading to the

FIG. 4. Radius of gyration R_g as a function of cosolvent fraction x_c for different cosolvent particle sizes.

polymer maintaining its collapsed conformation as soon as cosolvent particles are introduced. Snapshots at higher cosolvent fractions ($x_c > 0.6$) for $\sigma_c = 0.50$ and $\sigma_c = 2.00$ in Figure 5 illustrate this behavior: the polymer adopts a reentrant extended structure for large cosolvent particles ($\sigma_c = 2.00$), while maintaining a very compact structure for small cosolvent particles ($\sigma_c = 0.50$).

Importantly, the size asymmetry with the monomer is also a key factor, not just the size difference between solvent and cosolvent particles. As the cosolvent fraction x_c increases, the spatial distribution of solvent and cosolvent particles near the polymer surface varies, as illustrated by the radial distribution functions g_{pc} and g_{ps} for two different cosolvent particle sizes in Figure S4. For the $\sigma_c = 0.5\sigma_s$ case, increasing the cosolvent fraction leads to greater accumulation of cosolvent particles near the polymer, reaching a maximum at $x_c = 1$, driving the polymer into a highly compact state. In contrast, for $\sigma_c = 2.0\sigma_s$, no significant accumulation occurs near the polymer surface, even as x_c increases, allowing the polymer to remain extended. This can also be seen in the crossover of the number of solvent and cosolvent particles near the polymer as shown in Figure S5. For $\sigma_c = 0.5\sigma_s$, the crossover occurs at much smaller cosolvent fraction compared to the $\sigma_c = 2.0\sigma_s$ case. This behavior highlights how size asymmetry between solvent and cosolvent enhances depletion interactions when larger particles (solvent) cannot fit into regions between a polymer and smaller cosolvent particles. This creates an imbalance in osmotic pressure that exerts an attractive force between polymer segments, promoting collapse when the cosolvent size is smaller than the monomer. However, when the solvent and cosolvent particles are similar in size or larger than the monomer, size asymmetry does not lead to increased compaction, and the earlier observed reentrant extension occurs. This behavior reflects the complex interplay of polymer-crowder interactions, heavily influenced by both

FIG. 5. Snapshots of polymer at different cosolvent fraction x_c for cosolvent size $\sigma_c = 0.5\sigma_s$ and $\sigma_c = 2.0\sigma_s$.

the size and density of crowders. For instance, Kim et al. [44] examined the effect of crowder size on polymer conformation in cylindrical confinement and found that polymer chains collapse as the volume fraction of crowders increases, particularly when the crowder size is less than 0.6 times the monomer size. This aligns with classical polymer-crowder interaction theory, which posits that the free energy gain due to crowder exclusion is proportional to the polymer's surface area exposed to the solvent. Similarly, Jeon and colleagues [45] demonstrated that, for crowder sizes smaller than the monomer, polymer compaction is dependent on both the crowder size and density, whereas for larger crowders, compaction is primarily influenced by crowder density. This phenomenon is consistent with generalized depletion theory, which predicts that smaller crowders are more effective at inducing polymer collapse due to their ability to penetrate closer to the polymer surface.

C. Temperature and cononsolvency

Temperature plays a crucial role in determining the mixing behavior of solutions. In this study, we investigate the effect of temperature on the cononsolvency phenomenon driven by solvent-cosolvent attraction. The variation in the radius of gyration (R_a) with the cosolvent fraction (x_c) at different temperatures is presented in Figure 6(a). As temperature increases, we observe a diminishment in the cononsolvency effect. A similar trend is observed in the number of solvent and cosolvent particles in the vicinity of the polymer chain (Figure 6(b)), which reconfirms that, in the current model, cononsolvency is driven primarily by enhanced depletion effects arising from solvent-cosolvent attraction. At higher temperatures, the increased thermal energy results in greater entropy, causing particles to become more uniformly distributed around the polymer as opposed to lower temperatures, where both solvent and cosolvent particles are more excluded from the polymer surface. This leads to an extended polymer conformation at elevated temperatures, as seen from the conformations corresponding to $x_c = 0.5$, where cononsolvency is most pronounced (Fig-

FIG. 6. (a) Radius of gyration R_g as a function of cosolvent fraction x_c different temperature.(b) Number of solvents/cosolvents in contact with polymer within $1.5\sigma_s$ of polymer backbone.

ure 7(a)). Snapshots and radial distribution functions for solvent and cosolvent particles near the polymer surface (Figure 7(b)) also illustrate that, at lower temperatures, the particles are excluded from the polymer surface, while at higher temperatures, they decorate the polymer, leading to a more extended state.

To further investigate the effect of temperature on the cononsolvency behavior, we examine the enthalpic free energy contribution in the Flory-Huggins theory (F_{ϵ}) , shown in Figure 8. The plot demonstrates that as temperature increases, the enthalpic contribution to the free energy decreases, leading to the disappearance of the minima in the free energy landscape, which is consistent with our simulation results. This suggests that the depletion effect becomes less pronounced at higher temperatures, and the cononsolvency phenomenon fades. The reduction in depletion effects with increasing temperature has also been observed experimentally by Feng et al.[47]. Their study of colloid-polymer mixtures (Dextran and Polystyrene) showed that depletion is reduced at higher temperatures, particularly in systems where the interaction potential includes a soft component. Harries et al. [48–52] used Flory-Huggins energy expressions to explain how parameters such as cosolvent size, particle interactions, and mixing behavior can cause depletion to

FIG. 7. (a) The snapshots of polymer(solvent and cosolvent particles colored blue and green respectively) at different temperatures for cosolvent fraction $x_c = 0.5$ (b) Radial distribution function between polymer and solvent/cosolvent for cosolvent fraction $x_c = 0.5$

FIG. 8. The effect of temperature on interaction free energy from Flory-Huggins theory with ternary mixture. The plot shows as temperature increases, the contribution of inetraction free energy decreases and consistent with simulation results

be either enthalpic or entropic. In certain cases, depletion may be entropically disfavored but enthalpically favorable.

Experimental studies of protective osmolytes, such as trehalose and sorbitol, have shown that depletion can be enthalpically favorable but entropically unfavorable [48, 53, 54]. Harries and colleagues developed an entropy-energy plot to elucidate the balance between en-

tropic and energetic contributions to the stabilization free energy of the system. By incorporating non-zero entropic components in the free energy mixing parameters, they were able to access the enthalpic stabilization sector of the phase diagram. Even when solvent-cosolvent interactions are entropically disfavored on a microscopic scale, the energetic gain may still be sufficient to drive depletion. Our simple polymer model effectively captures the temperature dependence of cononsolvency and shows that the reduction in depletion effects with increasing temperature causes the disappearance of cononsolvency, particularly in the absence of preferential attraction between the polymer and cosolvent.

D. Preferential attraction and cononsolvency

In this section, we introduce preferential attraction between polymer and cosolvent, in addition to the existing attractive interactions between solvent and cosolvent particles, and explore its effects on cononsolvency within the present model. The preferential attraction of cosolvent particles to polymer segments can lead to effective bridging interactions. This occurs when cosolvent particles simultaneously interact with multiple polymer segments, effectively pulling them closer and promoting collapse, as seen in previous studies [18, 19, 27, 55]. We model the preferential polymer-cosolvent attraction using the Lennard-Jones potential with an interaction strength $\epsilon_{pc} = 4.0$, based on previous work where bridging interactions were shown to be effective [27]. The results of the polymer conformations, expressed through the radius of gyration (R_q) as a function of cosolvent fraction x_c , along with corresponding snapshots, are shown in Figure 9. As soon as attractive cosolvent particles are introduced, the polymer undergoes a coil-to-globule transition, driven by bridging interactions—an effective polymer-polymer attraction mediated by cosolvent particles. However, as the fraction of attractive cosolvent particles increases, the polymer-cosolvent interaction becomes increasingly preferable, leading to a globule-tocoil transition. This behavior aligns with the results of Mukherji et al. [33], who reported a similar smooth transition, albeit using a different model. While the preferential attraction of cosolvent to the polymer also induces cononsolvency, the underlying mechanism here differs significantly from the depletion-driven mechanism discussed in previous sections. In those cases, chain collapse was driven by enhanced depletion effects. In contrast, in the current scenario, cononsolvency is driven by bridging interactions [33]. In our earlier work [27], where we modeled the solvent implicitly, the polymer exhibited a coilto-globule transition as the attraction between polymer and cosolvent (crowders) increased. The reentrant behavior observed as the cosolvent fraction increases can be attributed to the fact that, as more cosolvents decorate the polymer chain, the polymer begins to favor an extended state. The location of the minimum in solvent

FIG. 9. Radius of gyration R_g as a function of cosolvent fraction x_c for preferential attraction. Attractive strength between monomer-coslovent is $\epsilon_{pc} = 4.0$. Snapshots of polymer (solvent and cosolvent particles colored blue and green respectively) at different cosolvent fraction x_c are also shown.

quality, In the case of preferential attraction as suggested by Zhang et al. [39], is given by:

$$x_c^* = \frac{1}{2} - \frac{2}{c\Delta\chi} \tag{4}$$

where $c = 1 - \phi_p$ and $\Delta \chi = \chi_{ps} - \chi_{pc}$, where χ_{ij} is Flory interaction parameter between component i and j [56]. For the preferential attraction case, $\Delta \chi$ is a non-zero positive value, leading to $x_c^* < 0.5$, which agrees with our simulation results. This finding is consistent with earlier studies where the collapse transition of a model polymer occurred at a lower cosolvent fraction for ethanol due to higher preferential adsorption of ethanol on the collapsed polymer globule [40, 57]. Additionally, stronger polymer-cosolvent attractions result in more extended polymer states beyond $x_c = 0.2$ in our work, explaining why poly(diethylacrylamide) (PDEA) does not exhibit cononsolvency in PDEA-methanol-water solutions [58–61].

IV. DISCUSSION AND CONCLUSION

We present a comprehensive study on the cononsolvency effect in linear polymers dissolved in a mixture of good solvents. Our simulation results demonstrate that solvent-cosolvent attraction alone is sufficient to induce the collapse of polymer chains in a mixture of two good solvents. Furthermore, our findings suggest that cononsolvency is a generic phenomenon, not restricted to specific chemical systems. When the polymer is dissolved in a solution containing only solvents, the chain adopts an extended conformation, as expected under good solvent conditions. Introducing cosolvents (c) with Weeks-

Chandler-Andersen (WCA) repulsive interactions with solvents does not alter this extended conformation. However, when solvent-cosolvent interactions become attractive, the polymer chain undergoes collapse as the cosolvent fraction increases, displaying cononsolvency behavior. The polymer reaches a fully compact state when the fractions of solvent and cosolvent are equal. This cononsolvency behavior is driven by the effective, enhanced depletion effect observed in our model. As the cosolvent fraction increases, both solvent and cosolvent particles are excluded from the polymer surface, leading to chain collapse. The attraction between solvent and cosolvent particles amplifies this depletion effect. In contrast, in other systems, solvent-cosolvent repulsion leads to a depleted depletion effect, resulting in cosolvency rather than cononsolvency [62].

The Flory-Huggins mean-field theory has been employed to explain cononsolvency behavior driven by solvent-cosolvent attraction [38]. Previous studies have derived expressions for the effective Flory-Huggins interaction parameter, showing that attractive interactions between solvent and cosolvent promote immiscibility [63– 65]. According to this theory, the minima of the free energy occur when the fractions of solvent and cosolvent are equal $(x_s = x_c = 0.5)$, corresponding to a relative solvent composition $\phi_c/\phi_s = 1$. This is consistent with our simulation results, where the variation in the polymer's radius of gyration follows the same trend as the energetic part of the free energy derived from Flory-Huggins theory. Plots of free energy as a function of relative solvent composition ϕ_c/ϕ_s suggest that the energetic term predominantly drives this behavior. Similarly, calculations by Zhang et al. [39] using the random phase approximation indicate that solvent quality is symmetric around $\phi_c/\phi_s=1$ for an equal-quality binary mixture, as predicted by Flory-Huggins theory and observed in our simulations. Unlike earlier simulations that used more complex models with specific interactions between polymer and solvent/cosolvent particles to demonstrate cononsolvency [33, 66–69], our results show that even a simple polymer model with minimal interactions can accurately match theoretical predictions and exhibit cononsolvency. In our system, cononsolvency is achieved without specialized interactions between the polymer and solvent particles, implying that modifying the effective attractions between solvent and cosolvent particles alone is sufficient to induce the phenomenon.

The size of solvent and cosolvent particles plays a crucial role in determining polymer conformation, particularly in driving cononsolvency behavior through solvent-cosolvent attraction. In our simulations, we find that when the cosolvent size is smaller than the polymer monomer size ($\sigma_c = 0.5\sigma_s$), the polymer remains collapsed for most cosolvent fractions, as the volume density exceeds the threshold necessary for inducing collapse. This behavior is consistent with depletion theory, which suggests that smaller particles create stronger depletion forces, leading to more effective polymer collapse [44,

45, 70, 71]. For larger cosolvent sizes ($\sigma_c = 1.0$ and 2.0), the polymer exhibits typical cononsolvency behavior—collapsing at intermediate cosolvent fractions and re-expanding at higher fractions. While the role of particle size in depletion effects has been extensively studied, such as by Kang et al. [70] and Sharp et al. [71], our results highlight that solvent-cosolvent attraction alone is sufficient to drive cononsolvency. In systems where the solvent and cosolvent particle sizes are comparable to the polymer monomer size, we observe that the polymer's conformation is highly sensitive to both size and the relative volume fraction of cosolvent. Jeon et al. [45] demonstrated that for crowders smaller than the polymer monomers, compaction is driven by both size and density, while larger crowders primarily depend on their density. The work of Kim et al. [44] and others emphasizes that smaller particles generate stronger depletion effects, which our study corroborates. Our results align with these findings, as smaller cosolvent particles induce polymer collapse at lower volume densities, while larger particles promote cononsolvency. This size-dependent behavior is critical for understanding cononsolvency in mixed solvent environments, where the interplay between solvent-cosolvent interactions and crowding effects becomes complex. We extend previous findings by showing that cononsolvency can be driven solely by adjusting solvent-cosolvent attraction and particle size, without requiring complex interaction models.

Traditionally, cononsolvency has been linked to smart polymers exhibiting lower critical solution temperature (LCST) behavior, such as PNIPAm, PVCL, or PA-POMe [72, 73]. This connection suggests that cononsolvency could be temperature-sensitive. Our simulations confirm this, showing that as temperature increases, the cononsolvency effect weakens. This reduction in cononsolvency corresponds to a more uniform distribution of solvent and cosolvent particles around the polymer chain, indicating that the depletion effect diminishes with rising temperature. This observation aligns with experimental findings from Feng et al. [47], who reported a similar decrease in depletion-induced polymer collapse in colloid-polymer mixtures at higher temperatures. Harries et al. [48, 49] used Flory-Huggins theory to show how depletion effects can be driven by both enthalpic and entropic contributions, depending on cosolvent size and interaction parameters. Certain depletants, such as trehalose and sorbitol, have been found to induce depletion primarily through enthalpic contributions. In our study, we observe a similar trend. As temperature increases, the interaction free energy term (\tilde{F}_{ϵ}) from Flory-Huggins theory decreases, indicating that the depletion effect is largely enthalpic and weakens with rising temperature. This temperature sensitivity underscores the role of enthalpic contributions in driving cononsolvency, further corroborating the temperature dependence observed in previous studies.

Previous studies on cononsolvency have primarily focused on systems where the cosolvent preferentially interacts with the polymer chain [33]. In such cases, cononsolvency is typically attributed to mechanisms like bridging interactions, where cosolvent particles act as connectors between different segments of the polymer, inducing collapse [19, 27, 55]. Another explanation involves the surfactant-like behavior of cosolvents, where the cosolvent reduces the free energy penalty associated with forming a repulsive polymer-solvent interface, driving polymer collapse at lower cosolvent fractions [40]. In contrast, our study demonstrates that cononsolvency can occur even in the absence of preferential interactions between the polymer and solvent/cosolvent. In our minimalistic model, cononsolvency arises solely from solventcosolvent attraction. However, introducing preferential interactions is an easier, more intuitive way to explore this phenomenon. When preferential attraction between the cosolvent and polymer is added, we observe cononsolvency at lower cosolvent fractions ($x_c < 0.5$), which aligns with previous work [39]. Our results are consistent with predictions from the random phase approximation, which suggests that the minima in polymer conformation for systems with preferential interactions occur in the range of $0.1 \le x_c < 0.5$, as we also observe in our simulations. Thus, while our model without preferential interactions demonstrates cononsolvency through solventcosolvent attraction alone, introducing these interactions leads to a different mechanism of cononsolvency that occurs at lower cosolvent fractions. This finding provides a direct comparison to prior studies, emphasizing that preferential interactions, while not necessary to induce cononsolvency, shift the cosolvent fraction at which polymer collapse occurs.

Cononsolvency challenges the expectation that a polymer, which remains extended in a good solvent, should behave similarly in a mixture of good solvents. Through a simple polymer model, we demonstrate that solvent-cosolvent attraction alone is sufficient to induce cononsolvency, without the need for complex interactions. While our findings contribute to the understanding of this phenomenon, developing a unified framework to predict cononsolvency across various systems and different polymer-solvent-cosolvent interactions, as well as refining this minimal model to explore other specific aspects, remains to be further explored.

ACKNOWLEDGMENT

We thank the HPC facility at the Institute of Mathematical Sciences for providing computing time. SV is grateful for the insightful and stimulating initial discussions with R. Rajesh, which critically contributed to the development of this work.
