(Dated: November 8, 2024)

The search for gravitational waves generated by the inspiral phase of binaries of light compact objects holds significant promise in testing the existence of primordial black holes and/or other exotic objects. In this paper, we present a new method to detect such signals exploiting some techniques typically applied in searches for continuous quasi-monochromatic gravitational waves. We describe the signal model employed and present a new strategy to optimally construct the search grid over the parameter space investigated, significantly reducing the search computing cost. Additionally, we estimate the pipeline sensitivity corroborating the results with software injections in real data from the LIGO third observing run. The results show that the method is well suited to detect long-transient signals and standard continuous gravitational waves. According to the criteria used in the grid construction step, the method can be implemented to cover a wide parameter space with slightly reduced sensitivity and lower computational cost or to focus on a narrower parameter space with increased sensitivity at a higher computational expense. The method shows an astrophysical reach up to the Galactic Center (8kpc) for some regions of the parameter space and given search configurations.

I. INTRODUCTION

The detection of gravitational waves (GWs) by the LIGO, Virgo and KAGRA collaborations (LVK) [\[1\]](#page-14-0) has increased the interest in searching for sub-solar mass compact objects, as their potential primordial origin offers insights into new physics. Primordial black holes (PBHs), hypothetical remnants of the early universe [\[2,](#page-14-1) [3\]](#page-14-2), are compelling because they are viable dark matter (DM) candidates and can shed light on the early universe condition and the formation of large-scale structures [\[4\]](#page-14-3). Unlike black holes formed through stellar evolution, PBHs could span a wide range of masses, from microscopic to supermassive [\[5–](#page-14-4)[8\]](#page-14-5). In principle, the direct detection of PBHs could be achieved through their gravitational wave signatures. When two PBHs merge, they emit GWs detectable by Earth-based interferometers [\[9–](#page-14-6)[11\]](#page-15-0). PBHs in binary systems could be identified by their unique merger rates, low masses and waveform characteristics, distinct from those of stellar-mass black holes [\[12,](#page-15-1) [13\]](#page-15-2). Population analyses of the GW events from the LVK transient catalogues [\[14–](#page-15-3)[16\]](#page-15-4) have not yet found any significant evidence of the presence of PBHs [\[17–](#page-15-5)[23\]](#page-15-6). The detection of a merger with at least one sub-solar component could be a definitive evidence of their existence. However, no PBH signal has been detected until now [\[24](#page-15-7)[–38\]](#page-16-0).

Another direct detection approach involves microlensing surveys. PBHs passing in front of a background of stars can cause a temporary increase in the star's brightness due to gravitational lensing. Projects like OGLE, MACHO, and EROS have conducted extensive microlensing surveys to constrain the abundance of PBHs in various mass ranges [\[39–](#page-16-1)[41\]](#page-16-2).

The most interesting regions to search for PBH signals are the ones where the DM abundance is expected to be high, such as globular clusters, galactic centers, dwarf spheroidal galaxies, DM halos or cosmic web filaments. The Milky Way center, harbouring the supermassive black hole Sagittarius A^* [\[42–](#page-16-3)[45\]](#page-16-4), is an ideal target for this investigation. The dense environment around the galactic center increases the likelihood of encounters between PBHs and other dark compact objects, leading to a higher chance of forming binary systems and enhancing the prospects of GWs detection [\[46\]](#page-16-5).

If PBHs exist in binaries, they could produce longtransient GWs during the inspiral phase of the coalescence [\[47\]](#page-16-6), emitting in the frequency band of Earth-based detectors. Typical methods used to search for compact binary coalescences (CBC) signals [\[14](#page-15-3)[–16\]](#page-15-4) are not optimal for signals that last longer than minutes and, therefore, techniques to search for more persistent signals might be preferred. Continuous GWs (CWs) lie in this category of long-lasting signals, typically having durations comparable with the run (from months to years) [\[48\]](#page-16-7). Several methods for the search of these fainter signals, deeply buried in the noise, have been developed over the years (see Refs. [\[48](#page-16-7)[–51\]](#page-16-8) for some recent reviews). These methods are routinely applied for the search of standard CW signals like those emitted by isolated nonaxisymmetric spinning neutron stars [\[52](#page-16-9)[–68\]](#page-17-0).

This paper outlines a new method to detect such longtransient signals originating from the inspiral of light

compact objects. The main novelty, with respect to existing methods [\[32,](#page-15-8) [37,](#page-16-10) [69](#page-17-1)[–73\]](#page-17-2), lies in the exploitation of the degeneracies of the signal waveform. This allows for the reduction of the problem's dimensionality and, hence, the decrease of the computing cost of the search.

The paper is organized as follows. Section [II](#page-1-0) introduces the signal that is being targeted and the model used in this work. Section [III](#page-1-1) provides an overview of the proposed method and the framework for the data analysis used. Section [IV](#page-7-0) describes how the candidates are selected and vetoed. Section V shows the sensitivity estimate of the method. Finally, Section [VI](#page-9-0) shows the results of an injection campaign over real O3 data.

II. SIGNAL

During the inspiral phase of a binary system of chirp mass \mathcal{M}_c , the two orbiting objects approach each other while radiating GWs. During this phase, their orbital frequency, and hence their GW frequency $f(t)$, increases as the objects get closer. In the Post-Newtonian (PN) formalism [\[47,](#page-16-6) [74,](#page-17-3) [75\]](#page-17-4), the 0PN approximation is the leading-order correction to the Newtonian gravitational dynamics. It can describe the relativistic effects in the case of low velocities and weak gravitational fields. Since the masses considered in this work are small $(< 10^{-3} M_{\odot})$ and we are targeting objects far from the coalescence, this approximation is within its range of validity. The signal amplitude is given by:

$$
h(t) = \frac{4}{d} \left(\frac{G \mathcal{M}_c}{c^2} \right)^{5/3} \left(\frac{\pi f(t)}{c} \right)^{2/3}, \quad (1)
$$

being d the luminosity distance to the source. The frequency evolution, for the case of objects in circular orbits, can be expressed as a power law [\[47\]](#page-16-6):

$$
\dot{f} = \frac{96}{5} \pi^{8/3} \left(\frac{G \mathcal{M}_c}{c^3}\right)^{5/3} f^n(t) = k f^n(t), \tag{2}
$$

with $n = 11/3$. Integrating Eq. [\(2\)](#page-1-2), the frequency of the emitted signal is

$$
f(t) = \left[f_0^{1/\alpha} + \frac{k}{\alpha} (t - t_0) \right]^\alpha , \qquad (3)
$$

where $\alpha = \frac{1}{1-n} = -3/8$ and f_0 is the frequency at a reference time, t_0 . It follows that the time to the merger will be

$$
t_{\rm merg} = \frac{f_0^{1/\alpha}}{(n-1)k} \ . \tag{4}
$$

Figure [1](#page-1-3) shows the merging time for systems emitting in the frequency range of Earth-based detectors and for chirp masses between $[10^{-6}, 10^{-3}]$ M_{\odot} . The typical duration of these signals is of the order $\mathcal{O}(\text{hours-months}).$

As a reference, all those systems with a greater merging time than 0.5 days lie below the black line. Large frequency variations are expected (e.g. $\sim 10^{-2}$ Hz/s for a system with a chirp mass of 10^{-3} M_{\odot} at around 300 Hz), well above the typical values covered in standard CW scenarios (the maximum frequency variation is - in absolute value - 10^{-8} Hz/s). On the other hand, systems with small chirp masses have frequency variations comparable with more standard CWs .^{[1](#page-1-4)} For instance, variations of $\sim 10^{-9}$ Hz/s are expected from sources with $\mathcal{M}_c \sim 10^{-6}$ M_\odot at 100 Hz.

FIG. 1. Merging time since t_0 in seconds. The black line indicates the curve corresponding to a $t_{\text{merg}} = 0.5$ days.

Due to the Earth's orbital and rotational motions, the signal that reaches the detector will be affected by the Doppler effect, resulting in a frequency modulation of:

$$
f_d(t) = f(t) \left(1 + \frac{\vec{v} \cdot \hat{n}}{c} \right) , \qquad (5)
$$

where \vec{v} is the detector velocity and \hat{n} is the unitary vector pointing to the source, in the Solar System barycenter reference frame. The Doppler contribution can be neglected for sufficiently short signals or particular choices of the search setup (see Sec. [III D\)](#page-4-0).

III. METHOD

As already mentioned, several CW detection methods exist, each prioritizing either the sensitivity, the computing cost or the pipeline's robustness. Typical CW signals are characterized by their long duration $\mathcal{O}(\text{months})$

¹ It should be noted, however, that in standard CW searches for spinning neutron stars, the signal is modelled with a spin-down rather than a spin-up, but from a technical point of view some search methods can be directly applied to spinning up sources with minimal adjustments.

or years), and a low signal-to-noise ratio if compared with transient signals emitted e.g. during the coalescence of two compact objects. The category of signals we are interested in this work lies in between transients and purely CWs with a duration of the order $\mathcal{O}(\text{hours-days})$ (See Sec. [II\)](#page-1-0). Optimal methods like matched filtering - typically applied for the search for transients CBC signals might be unfeasible for wide parameter space searches. This also applies to the long-transient regime considered in this work. For this reason, we developed a new semicoherent method to detect long-transient CW signals, exploiting the signal's parameter degeneracy to reduce the computing cost of the search. The method leverages on some standard CW search techniques, like the heterodyne demodulation procedure - adapted to the case of study - to increase the signal-to-noise ratio [\[76,](#page-17-5) [77\]](#page-17-6). In the following subsections, we will explain each step of the proposed method to search for this family of CWtransients signals.

A. Data framework

For this work, the Band Sampled Data (BSD) framework and libraries are used [\[76\]](#page-17-5). The BSD files are bandlimited time series, down-sampled and divided into frequency sub-bands, partially cleaned from instrumental disturbances. The most recent version of the high-latency O3 calibrated gated data [\[78–](#page-17-7)[81\]](#page-17-8) was used for the injection analyses described in Sec. [VI.](#page-9-0) Additionally, only science segments - defined as time intervals during which the detector operated nominally with acceptable noise levels - were selected [\[82\]](#page-17-9). The BSD files benefit from the removal of short-duration noise transients as in [\[83\]](#page-17-10). The data structures contain the reduced-analytic straincalibrated time series of the LIGO and Virgo detectors. This data package allows for fast and flexible data management that reduces the computational cost of the analysis. In particular, the framework allows to construct input data either as long segments over small frequency bands or as short periods covering large frequency bands. To date, several CW searches have been performed using the BSD library, mostly using the long-time/narrowfrequency band configuration [\[52,](#page-16-9) [63,](#page-16-11) [84](#page-17-11)[–87\]](#page-17-12), including those for DM candidates from superradiant boson clouds [\[88\]](#page-17-13) or dark photon DM [\[89\]](#page-17-14).

As shown in Fig. [1](#page-1-3) we are interested in signals with durations considerably shorter than standard CW signals. Therefore, we will handle the data in the BSD short-time/wider-frequency band configuration. In practice, the data will be cut in time chunks of length T_{obs} . The total number of periods to be analyzed will then be $N_T = T_{\text{run}}/T_{\text{obs}}$, where T_{run} is the total time of the observing run. This number is effectively reduced when each interferometer's duty cycle is considered. Typically, a detector is not taking data continuously or its quality is not good enough for science mode, therefore, in nonscience periods there will be gaps in the data. A reasonable choice would be to discard those batches of time containing more than 40% of non-science data, avoiding processing unnecessary chunks of time.

B. Heterodyne correction

As explained in Sec. [II,](#page-1-0) long-transient signals may span a wider frequency band than standard CW sources. To reduce its spread across the frequency band, we employ the heterodyne phase correction, which enhances the signal-to-noise ratio and improves detectability [\[76,](#page-17-5) [77\]](#page-17-6) to demodulate the signal. This will allow us to use an excess power method to identify significant candidates in the frequency domain (see Sec. [III D\)](#page-4-0). In the following, a short description of the heterodyne phase correction is provided.

For simplicity, the signal can be written as $s(t)$ = $A(t)e^{i\phi(t)}$, where $A(t)$ is its amplitude and $\phi(t)$ its phase. The phase is related to the frequency evolution of the source as

$$
\frac{\mathrm{d}\phi}{\mathrm{d}t} = 2\pi f(t). \tag{6}
$$

Therefore, the phase evolution of a signal, $\phi_s(t)$, will be

$$
\phi_s(t) = \frac{2\pi}{k(2-n)} f^{2-n}(t).
$$
 (7)

If we include the Doppler contribution the phase will be $\phi(t) = \phi_s(t) + \phi_d(t)$, and can be computed as

$$
\phi_d(t) = 2\pi \int_{t_0}^t f(t') \frac{\vec{v} \cdot \hat{n}}{c} dt'
$$
 (8)

as discussed in Ref. [\[76\]](#page-17-5).

The measured and calibrated strain of an interferometer $h(t)$ will be a combination of the signal $s(t)$ and the noise $n(t)$. In general, the noise can be non-stationary and non-Gaussian, but during short periods of time (of the order of some minutes at maximum), it can be assumed as stationary.

The heterodyne phase correction can now be applied to the strain data as

$$
h_{\text{het}}(t) = h(t)e^{-i\phi_{\text{corr}}(t)} , \qquad (9)
$$

where $\phi_{\text{corr}}(t) = \phi(t) - 2\pi f_0 t$. The effect of this correction is to modify the strain to

$$
h_{\text{het}}(t) = A(t)e^{i2\pi f_0 t} + n(t)e^{-i\phi(t)}, \qquad (10)
$$

which implies that the signal has been converted to a purely monochromatic one (with a frequency of f_0) up to some residual modulations. These residual modulations could manifest in the case of incorrect modelling of the frequency evolution or if the assumed source sky position is incorrect (e.g. if the Doppler contribution is not negligible).

C. ξ−space

As shown in Eq. [\(7\)](#page-2-0), the signal phase, besides being a function of time, depends on the two source parameters (f_0, \mathcal{M}_c) at the reference time t_0 . At first glance, performing the heterodyne correction with different combinations of (f_0, \mathcal{M}_c) might seem sufficient to complete the search. However, this approach would not only be highly computationally demanding, but it also overlooks the fact that various parameter combinations can result in nearly identical frequency evolutions. Indeed, multiple combinations of (f_0, \mathcal{M}_c) might produce the same $\phi_s(t)$ and, hence, a single heterodyne correction would be enough to correct for more than one point in the (f_0, \mathcal{M}_c) plane [\[90\]](#page-17-15).

Without loss of generality, we can define a new variable, ξ , that measures the relative increment of frequency during the observing time T_{obs} :

$$
\xi(f_0, \mathcal{M}_c, T_{\text{obs}}) = \left[f_0^{1/\alpha} + \frac{k}{\alpha} T_{\text{obs}}\right]^\alpha - f_0 \ . \tag{11}
$$

This variable depends only on the reference frequency and chirp mass for a fixed observing time. Therefore, it maps the two-dimensional parameter space into the ξ −space. In Fig. [2](#page-3-0) a plot containing the iso- ξ curves is presented for a fixed T_{obs} . Due to the 0PN model used for the frequency evolution, which is only valid for the inspiral part of the signal and not the merger, ξ can diverge, as the frequency grows exponentially fast when it gets very close to the merger, or even take imaginary values if the argument inside the brackets becomes negative. We will therefore set a maximum frequency shift to avoid such divergences and imaginary values, these systems correspond to those with a merger time shorter than T_{obs} . As T_{obs} increases, the magnitude of ξ decreases and the slope of the curves $\mathcal{M}_c = \mathcal{M}_c(f_0, \xi, T_{\text{obs}})$ also decreases. Furthermore, higher frequencies and chirp masses in the upper right region of the parameter space become inaccessible, as ξ takes imaginary values. Therefore, increasing T_{obs} allows more signals to merge within this time frame, which reduces the parameter space that can be effectively probed.

Equation [\(11\)](#page-3-1) can be inverted to find the values of \mathcal{M}_c as a function of ξ and the frequency f_0 . This is

$$
\mathcal{M}_c(\xi, f_0, T_{\text{obs}}) = \frac{c^3}{G} \left[\frac{5\alpha}{96\pi^{8/3}} \frac{(\xi + f_0)^{1/\alpha} - f_0^{1/\alpha}}{T_{\text{obs}}} \right]^{3/5}.
$$
\n(12)

While no analytical expression for $f_0 = f_0(\xi, \mathcal{M}_c, T_{obs})$ exists, Eq. [\(12\)](#page-3-2) can be numerically interpolated up to machine precision, to find the corresponding value of f_0 .

In Fig. [3](#page-3-3) we show a comparison of the frequency and phase evolution for two signals belonging to the same iso- ξ curve at $\xi = 0.5$ Hz with the following characteristics:

- Signal 1: $f_0 = 57.21$ Hz, $\mathcal{M}_c = 8.12 \times 10^{-4} M_{\odot}$.
- Signal 2: $f_0 = 254.87$ Hz, $\mathcal{M}_c = 3.06 \times 10^{-5} M_\odot$.

FIG. 2. Iso-ξ curves inside the region of the parameter space of interest with a fixed $T_{\text{obs}} = 0.5$ days.

The frequencies and chirp masses of these signals are randomly chosen, but such that they keep the same value of ξ.

As it is observed, despite having very different parameters their relative frequency and phase evolve very similarly as the two signals belong to the same iso- ξ curve. Given this phase evolution degeneracy, a unique heterodyne correction using a single set of (f_0, \mathcal{M}_c) can be applied to the data to demodulate signals that belong to the same iso- ξ curve.

FIG. 3. Comparison of the frequency and phase evolution of two signals with parameters $f_0 = 57.21$ Hz, $\mathcal{M}_c = 9.12 \times$ $10^{-4}M_{\odot}$ (Signal 1) and $f_0 = 254.87$ Hz, $\mathcal{M}_c = 3.06 \times 10^{-5}M_{\odot}$ (Signal 2). The signals lie on the same iso- ξ curve $\xi = 0.5$ Hz. Here ϕ_0 is the phase at t_0 .

Multiple iso-ξ injections with different (f_0, \mathcal{M}_c) parameters are performed to show the method's validity. In Fig. [4,](#page-5-0) we show the power spectra of four different injections belonging to $\xi = 1$ Hz with a very high signal-to-noise ratio for illustrative purposes. In blue, we display the power spectra of the data containing a signal before applying the demodulation, while in black, we show the spectra after applying the same heterodyne correction to the four different datasets. Additionally, we include in green the power spectrum obtained correcting the signal with the exact parameters of the injection. The injection parameters are reported in Tab. [I.](#page-4-1) The reference time for the starting frequency f_0 is $t_0 = 1238198418$ s and the signals are injected in a chunk of data from the third observing run (O3) of the LIGO Livingston detector. We also report the degree of polarization $\eta = -2 \cos \iota/(1 + \cos^2 \iota)$, which is a function of the inclination angle of the binary's orbit, ι . For simplicity, we inject all the signals at the sky location of the Galactic Center ($\alpha = 94.969^{\circ}$ and $\delta = 17.3432^{\circ}$).

	Signal $ f_0$ [Hz] $\vert M_c$ [M _o] $ d$ [kpc] $ $		η	ψ
	67.19 $ 8.58 \times 10^{-4} $	0.1	$-0.85 8.9^{\circ}$	
$\bf{2}$	75.30 (6.69×10^{-4})			
3	86.17 $ 4.98 \times 10^{-4}$			
	98.94 $ 3.68 \times 10^{-4}$			
	$(\widehat{f}_0, \widehat{\mathcal{M}}_c)$ 106.97 3.10 \times 10 ⁻⁴			

TABLE I. Parameters of the 4 signals injected in the O3 Livingston data and shown in Fig. [4.](#page-5-0) All the signals lie on the same ξ curve of value $\xi = 1$ Hz. The last row reports the parameter used for the correction.

All of the power spectra in Figure [4,](#page-5-0) show a clear peak at the frequency of the injected signal after applying the heterodyne demodulation using (f_0, \mathcal{M}_c) . Despite having very different parameters, the method is, in fact, capable of correctly demodulating signals along a single iso- ξ line. As a reference, we report the power spectra of the signal corrected using the exact parameters of the injection. We notice that no significant power loss is shown for these injections.

D. Time-frequency map creation

After the time series has been corrected using the heterodyne, it can be mapped into the time-frequency plane. This is done by creating the so-called peakmap, which contains a collection of the most significant timefrequency peaks [\[83\]](#page-17-10). These peaks are local maxima selected above a given threshold of the ratio between the modulus of the Fast Fourier Transform (FFT) and an estimation of the average spectrum (see Ref. [\[91\]](#page-17-16)). The duration of the FFT, is referred to as the coherence time $(T_{\rm coh})$, and the starting time corresponds to the time associated with the selected peak.

The threshold for selecting a peak significantly affects the probability of detecting a signal or missing it. In this method, the peakmap threshold is set to 2.5, as in Ref. [\[91\]](#page-17-16). Once the peakmap is created, it is projected onto the frequency axis, and a histogram is generated showing the number of peaks n in each frequency bin. The significance of the peaks in a frequency bin, which may indicate the presence of a signal, is determined by the critical ratio (CR), given by:

$$
CR = \frac{n - \mu}{\sigma} \,,\tag{13}
$$

being μ the mean of n and σ its standard deviation. This is a standard statistic employed to select the first-level candidates (See e.g. [\[91\]](#page-17-16)). All the candidates with CR values above a given threshold are selected and passed to the following post-processing phase discussed in section [IV.](#page-7-0)

An example showing an injection of a signal in real O3 data of LIGO Livingston between GPS times $t =$ 1238198418 s and $t = 1238241618$ s, frequencies $f =$ 20 Hz and $f = 360$ Hz, and $T_{coh} = 432$ s is displayed in Fig. [5.](#page-5-1) The injection parameters are $f_0 = 167.58$ Hz, $\mathcal{M}_c = 5.67 \times 10^{-4} M_{\odot}$, $d = 1$ kpc. In this figure, the peakmaps and the CRs for the original data, the data with the signal injected and the data after the heterodyne correction has been applied are shown to demonstrate the effect of heterodyning. After the heterodyne (righthand column), the signal becomes visible as a horizontal line around the reference frequency and it can also be identified as a high-significance candidate in the CR plot.

1. Limits on the peakmap resolution

The natural frequency bin resolution of the peakmap has a width of $\delta f = 1/T_{\text{coh}}$. In any semi-coherent search, the duration of the coherence time, T_{coh} , impacts the the duration of the conerence time, I_{coh} , impacts the sensitivity of the search, scaling as $1/\sqrt[4]{T_{\text{coh}}}$, but also its computing cost, which scales at least as T_{coh}^2 . For this reason, given the computing limitations, using extremely long T_{coh} is generally not feasible and a maximum coherence time should be set. On the other hand, there are also restrictions on how short this length can be. If T_{coh} is too short, there will be fewer frequency bins which can lead to poor statistics when computing the CR. Furthermore, if the T_{coh} is too short, FFT-based methods are not optimal unless properly adapted, as they are more suitable for analyses of longer data chunks. Different arguments can be used to set the minimum coherence time. One possibility is to check the errors of the estimators of the mean and standard deviation used to compute the CR. As detailed in Appendix [A,](#page-12-0) we find that for a search using $T_{\text{obs}} = 0.5$ days, the minimum coherence time that can be used is ~ 1.7 s while the maximum is ~ 432 s. We note that, with these constraints, the Doppler modulation can be neglected.

FIG. 4. Power spectrum of the strain for injected signals with parameters in Tab. [I.](#page-4-1) For each signal, the red cross indicates the maximum of the power spectrum after the correction has been applied. The green line shows the power spectrum after correcting the data with the exact parameters of the original injection. The black line shows the power spectrum after correcting the data using $(\hat{f}_0, \hat{\mathcal{M}}_c)$. The *blue* curve is the original power spectrum when no demodulation is applied.

FIG. 5. (Upper row) Example of peakmaps built from real O3 data from LIGO Livingston. The left plot shows the original peakmap (noise-only), the middle plot contains the same data with an injected signal (uncorrected), and the right plot presents the results after applying the heterodyne correction. We use data between GPS times $t = 1238198418$ s and $t = 1238241618$ s, covering frequencies from $f = 20$ Hz to $f = 360$ Hz, with a coherence time $T_{coh} = 432$ s. The injection parameters are: $f_0 = 167.58$ Hz, $\mathcal{M}_c = 5.67 \times 10^{-4} M_\odot$, $d = 1$ kpc, $\alpha = 94.969^\circ$, and $\delta = 17.3432^\circ$. (*Lower row*) The plots illustrate the CRs computed from each peakmap. Candidates with CR> 5 are marked with red crosses in all three cases.

E. Grid on ξ : variable T_{coh}

The optimal values for T_{coh} can be set assuming that, after applying the partial correction using a given $(\widehat{f}_0, \widehat{\mathcal{M}}_c)$, the signal will be fully confined in a single frequency bin, i.e., T_{coh} should satisfy the following condition, for two pairs (f_0, \mathcal{M}_c) and (f'_0, \mathcal{M}'_c) of the same ξ during $T_{\rm obs}$:

$$
\mathcal{G}(\xi, f_0, f'_0) = \max_{t \in [t_0, t_0 + T_{\text{obs}}]} |f(t) - f'(t) - f_0 + f'_0| \le \frac{1}{T_{\text{coh}}}.
$$
\n(14)

This can be interpreted as the maximum possible relative distance in frequency between two signals that have the same frequency increment in T_{obs} as depicted in Fig. [6.](#page-6-0)

Equation (14) has an analytical solution for t at

$$
t_{\max} = \frac{f_0^{1/\alpha} - \left(\frac{k'}{k}\right)^{\frac{1}{\alpha n}} f_0'^{1/\alpha}}{(1-n) \left[\left(\frac{k'}{k}\right)^{\frac{1}{\alpha n}} k' - k\right]},
$$
 (15)

where k is the function of the chirp mass in Eq. [\(2\)](#page-1-2).

FIG. 6. Comparison of the relative difference in the frequency evolution of two signals with parameters $f_0 = 57.21$ Hz, \mathcal{M}_c = $9.12 \times 10^{-4} M_{\odot}$ (Signal 1) and $f_0 = 254.87$ Hz, $\mathcal{M}_c = 3.06 \times$ $10^{-5}M_{\odot}$ (Signal 2). The signals lie on the same iso-ξ curve $\xi = 0.5$ Hz. The dashed vertical line is the time at $t = t_{\text{max}}$ as in Eq. [\(15\)](#page-6-2).

It should be noted that signals corresponding to more distant points on the iso- ξ curve are less similar to each other (due to the dependence of \dot{f} on f_0 and \mathcal{M}_c (see Eq. (7)). In particular, the coherence time must be adjusted to ensure effective signal demodulation for all points on the iso- ξ curve. Specifically, a shorter coherence time is more optimal to cover the wider frequency variations.

Since we want to still use the maximum possible coherence time, a compromise is to choose the point where the variation of signal properties is minimal compared to the rest of the points on the same iso- ξ (see Appendix [B](#page-13-0) for the details on the grid construction). This approach is the one that creates the smallest possible grid that covers the full parameter space as it only places one point per iso-ξ line while keeping the maximum possible T_{coh} . A downside of this approach is that if $T_{\text{coh}} \gtrsim 1/\Delta f_d^{\text{max}}$ (Eq. [\(A1\)](#page-12-1)) the Doppler modulation should be also included in the phase correction increasing the cost of the search. Furthermore, the limitations on the peakmap construction discussed in Sec. III D_1 , should also be taken into account. Additionally, for higher values of ξ , i.e. for signals with wide frequency variations, the placement of a single (f_0, \mathcal{M}_c) point would allow for maximum values of the T_{coh} that are too small to meet the minimum coherence time requirements discussed in Sec. [III D 1.](#page-4-2) Hence, a maximum ξ will be set for this type of grid, limiting the parameter space that can be investigated. The grid obtained with $f_0^{\text{min}} = 10$ Hz, $f_0^{\text{max}} = 300$ Hz, ${\cal M}^{\rm min}_{\rm c} = 10^{-6}~M_\odot,~{\cal M}^{\rm max}_{c} = 10^{-3}~M_\odot,~T^{\rm max}_{\rm coh} = 432~{\rm s},$ $T_{\text{coh}}^{\text{min}} = 1.7 \text{ s}, \xi^{\text{min}} = 10^{-8} \text{ Hz}, \xi^{\text{max}} = 10 \text{ Hz} \text{ is displayed}$ in Fig. [7a.](#page-7-1) It contains 851 points in total. In Fig. [7b](#page-7-2) we see that for smaller values of ξ , i.e. for signals having lower spin-up during T_{obs} , the largest T_{coh} allowed by the grid is larger than the maximum T_{coh} needed for the peakmap construction (see Sec. [III D 1\)](#page-4-2), hence a limiting $T_{\rm coh}$ is set at 432 s. The cutoff at $\xi \gtrsim 10$ Hz corresponds to signals that cannot be handled with a single correction with the minimum T_{coh} specified.

Given the limitations on the parameter space that can be covered by placing a single (f_0, \mathcal{M}_c) point, an alternative grid can be constructed to densely cover the parameter space of interest, as discussed in the following section.

F. Grid on ξ : fixed T_{coh}

Let us now consider the case of a grid constructed using the maximum possible T_{coh} as discussed in Sec. [III D 1,](#page-4-2) dropping the requirement of having a single grid point per iso-ξ. In this setup, the only requirement is that $\Delta \xi =$ $1/T_{\text{coh}}$. For each iso-ξ line, the grid is populated starting from the maximum frequency $f_i = f_0^{\text{max}}$ of the parameter space of interest. The corresponding chirp mass value \mathcal{M}_c^i is then obtained by evaluating $\mathcal{M}_c(\xi, f_0^i, T_{obs})$ $(Eq. (12))$ $(Eq. (12))$ $(Eq. (12))$. This will be the maximum chirp mass covered on that specific iso- ξ line. As long as the condition in Eq. [\(14\)](#page-6-1) holds, no further pairs of (f_0, \mathcal{M}_c) are placed on the same iso-ξ. If this condition is no longer valid, the next pair of (f_0, M_c) , i.e. (f_0^{i+1}, M_c^{i+1}) are placed by solving $\mathcal{G}(\xi, f_0^i, f_0^{i+1}) = 1/T_{\text{coh}}$. This operation is iterated as long as the minimum frequency of the parameter space of interest is reached. The full operation is repeated for the next ξ line. The complete algorithm is described in Appendix [2\)](#page-14-7). This grid construction method, as it

FIG. 7. Grid with variable T_{coh} and $f_0^{\text{min}} = 10$ Hz, $f_0^{\text{max}} = 300$ Hz, $\mathcal{M}_c^{\text{min}} = 10^{-6}$ M_{\odot} , $\mathcal{M}_c^{\text{max}} = 10^{-3}$ M_{\odot} , $T_{\text{coh}}^{\text{max}} = 432$ s, $T_{\text{coh}}^{\text{min}} = 1.7 \text{ s}, \, \xi^{\text{min}} = 10^{-8} \text{ Hz}, \, \xi^{\text{max}} = 10 \text{ Hz}.$

can keep the T_{coh} to any arbitrary level, can be used to reach a desired sensitivity at the expense of increasing the computational cost.

In Fig. [8,](#page-7-3) a grid with $f_0^{\min} = 10$ Hz, $f_0^{\max} = 300$ Hz, ${\cal M}^{\rm min}_c \ = \ 10^{-6} \ \, M_{\odot}, \ \, {\cal M}^{\rm max}_c \ = \ 10^{-3} \ \, M_{\odot}, \ \xi^{\rm min} \ = \ 10^{-8}$ Hz and $\xi^{\text{max}} = 10$ Hz is shown when keeping the target coherence time to $T_{\text{coh}}^{\text{tar}} = 432 \text{ s.}$ This grid contains a total of 1.75×10^5 points.

FIG. 8. Grid with constant T_{coh} and $f_0^{\text{min}} = 10$ Hz, $f_0^{\text{max}} =$ 300 Hz, $\mathcal{M}_c^{\min} = 10^{-6} M_{\odot}$, $\mathcal{M}_c^{\max} = 10^{-3} M_{\odot}$, $T_{\text{coh}}^{\text{tar}} = 432$ s, $\xi^{\min} = 10^{-8}$ Hz, $\xi^{\max} = 10$ Hz.

To compare the number of points of this grid to other approaches, we can take as an example the work from Ref. [\[72\]](#page-17-17), where a more standard grid has been constructed using a frequency spacing of 10^{-2} Hz and of chirp mass of $10^{-7} M_{\odot}$. The grid used in that study does not exploit the signal degeneracies and contains 2.9×10^8 points. Therefore, our grid is already three orders of magnitude smaller than a typical grid size for a search of this kind.

IV. CANDIDATES POST-PROCESSING

As detailed in Sec. [III D,](#page-4-0) once the search is performed on the dataset of duration T_{obs} , a set of first-stage set of candidates is selected. Here, dataset refers to a data segment of duration T_{obs} being analyzed. For a single detector there can be up to N_T datasets (see Sec. [III A\)](#page-2-1). In case of two (or more) detectors, additional sets of candidates can be obtained. Below, we describe how to combine results from multiple datasets, whether from the same or different detectors.

A. Coincidence between datasets

For a given dataset, each candidate is associated with a pair of frequency and chirp mass, but, after heterodyning, the recovered frequency is that of the signal at the start of the chunk of data analyzed i.e., t_i , which may not coincide with the reference time t_0 . Since most of the signals searched are longer than T_{obs} , multiple triggers might arise for the same signal at different periods of $T_{\rm obs}$ analyzed.

The different candidates from the various periods might belong to the same signal if they match the same frequency evolution of Eq. (3) . To check this, we update all the candidate parameters to the same reference time t_0 according to Eq. [\(3\)](#page-1-5).

Aligning all candidate parameters to the same reference time facilitates the tracking of data from different time segments and enables the combination of information from multiple interferometers. In case two candidates belong to the same signal, once updated to their value at t_0 , they should be close in the (f_0, \mathcal{M}_c) space.

To quantify this, we can compute the distance between these candidates as the L_2 -norm considering the spacing of the grid, df_0 and $d\mathcal{M}_c$, as

$$
D = \sqrt{\left(\frac{f_0 - f_0'}{\mathrm{d}f_0}\right)^2 + \left(\frac{\mathcal{M}_c - \mathcal{M}_c'}{\mathrm{d}\mathcal{M}_c}\right)^2},\qquad(16)
$$

where $df_0 = 1/T_{coh}$ and taking into consideration that $d\xi = \frac{\partial \xi}{\partial f_0} df_0 + \frac{\partial \xi}{\partial M_c} dM_c$ and that also equals $d\xi =$ $1/T_{\text{coh}}$, the value of $d\mathcal{M}_c$ can be obtained. From Eq. [\(11\)](#page-3-1) the partial derivatives can be evaluated and equal

$$
\frac{\partial \xi}{\partial f_0} = f_0^{\frac{1-\alpha}{\alpha}} \left(f_0^{\frac{1}{\alpha}} + \frac{k}{\alpha} T_{\text{obs}} \right)^{\alpha - 1} - 1 ,
$$

$$
\frac{\partial \xi}{\partial M_c} = 32\pi^{\frac{8}{3}} T_{\text{obs}} \left(\frac{G}{c^3} \right)^{\frac{5}{3}} M_c^{\frac{2}{3}} \left(f_0^{\frac{1}{\alpha}} + \frac{k}{\alpha} T_{\text{obs}} \right)^{\alpha - 1} .
$$

The primed and unprimed quantities denote the recovered parameters for the two candidates (belonging to two different detectors or two data chunks of the same detector). A pair of candidates is found in coincidence when $D < 4$, a typical value used in other searches [\[63,](#page-16-11) [91\]](#page-17-16).

For real signals, we expect to have coincident candidates from two different detectors over the same T_{obs} . For candidates from different T_{obs} and the same detector, we expect to have coincidences as long as their time to the merger is compatible with the total observing time (e.g. $t_{\text{merg}} \geq 2T_{\text{obs}}$ for 2 data chunks, etc.). Non-coincident candidates with $t_{\text{merg}} \leq 2T_{\text{obs}}$ are currently discarded. Requiring candidates to survive this stage before going to the next veto step will reduce the false positives of the search.

B. Candidate vetoes and follow-up

Vetoes: Once the first level of coincident candidates is produced, these undergo a multi-stage veto procedure.

One standard veto step is to check the consistency of the candidate's significance in each of the detectors [\[52,](#page-16-9) [62,](#page-16-12) [63\]](#page-16-11). This is achieved by discarding all coincident candidates where the weighted CR in the less sensitive detector is more than three times higher than in the more sensitive detector. Practically, assuming the noise spectral density in the first detector is worse, i.e., $S_{n_1}(f) > S_{n_2}(f)$, only the outliers satisfying $CR_1/\sqrt{S_{n_1}(f)} < 3CR_2/\sqrt{S_{n_2}(f)}$ move on to the next post-processing step. This veto step applies only to candidates found in coincidence between datasets from different detectors, not to those arising from coincidences between two consecutive data chunks.

Instrumental artifacts, such as spectral lines and glitches, degrade the detector's data quality [\[78,](#page-17-7) [92–](#page-17-18)[96\]](#page-17-19). The impact of glitches is mitigated by applying various cleaning procedures to the data [\[76\]](#page-17-5). However, instrumental lines are not removed from the data before

the analysis begins, hence some of the candidates that passed the first selection might have been produced by these lines. However, it is important to note that many of the signals we are targeting span a wide frequency band. Removing outliers whose frequency intersects with the frequency region contaminated by a known noise line [\[93,](#page-17-20) [97,](#page-17-21) [98\]](#page-17-22) is not advisable, as it would eliminate a significant portion of the selected candidates, potentially causing us to miss real signals. A safer procedure is to verify that there are no known spectral lines in the same frequency bin of the candidate at t_0 before applying the heterodyne correction. We can study the peakmap projection of the original data and verify where the spectral lines are originally located. This is especially important for checking the presence of wandering or transient lines that might be present only in the data chunk T_{obs} . This procedure should be repeated for each set of surviving candidates in every one of the N_T analyzed chunks and for each detector.

Finally, another veto procedure involves checking if the candidate's significance, computed using the demodulated data with the parameters (f_0, \mathcal{M}_c) , increases compared to the significance computed on the same frequency bin using the uncorrected time series. This check applies to the coincidences between two detectors and between multiple chunks. Once the candidates survive these veto steps, they can pass to the follow-up stage.

Follow-up: A potential follow-up stage involves creating a refined grid around the candidate's parameters (f_0, \mathcal{M}_c) . This grid can be uniform in f_0 and \mathcal{M}_c , utilize longer T_{coh} and T_{obs} , and possibly incorporate the Doppler modulation of the signal if required. The refined grid helps to accurately determine the true parameters of the signal. For candidates found in multiple subsequent chunks, we can estimate the total signal duration and apply more suitable matched-filter techniques. The details of the specific follow-up procedures to be used in a real search are beyond the scope of this paper and will be addressed in future work.

V. SENSITIVITY ESTIMATE

In this section, the theoretical sensitivity of the method is analytically estimated. Following the approaches in [\[63,](#page-16-11) [91\]](#page-17-16), for a peakmap-based search, the minimum detectable strain (at $\Gamma = 0.95$ confidence level), is

$$
h_{0,\min}(f) = \mathcal{B}\left(\frac{T_{\text{coh}}}{T_{\text{obs}}}\right)^{\frac{1}{4}} \sqrt{\frac{S_n(f)}{T_{\text{coh}}}} \sqrt{\text{CR}_{\text{thr}} - \sqrt{2}\text{erfc}^{-1}(2\Gamma)},\tag{17}
$$

where $S_n(f)$ is the power spectral density of the noise in the interferometer and β is a parameter that depends on the sky position, the threshold used for peak selection in the peakmap and the polarization of the signal, which for this case is averaged. For an all-sky search, this is equal to $B = 4.97$ [\[91\]](#page-17-16).

Equating Eqs. (17) and (1) , the maximum reachable distance of the search is

$$
d_{\text{max}} = \frac{4}{\mathcal{B}} \left(\frac{G\mathcal{M}_c}{c^2}\right)^{5/3} \left(\frac{\pi f_0}{c}\right)^{2/3} \left(\frac{T_{\text{obs}}}{T_{\text{coh}}}\right)^{1/4}
$$

$$
\times \sqrt{\frac{T_{\text{coh}}}{S_n(f)}} \left[\text{CR}_{\text{thr}} - \sqrt{2}\text{erfc}^{-1}(2\Gamma)\right]^{-1/2} . \quad (18)
$$

In Fig. [9](#page-10-0) the maximum reachable distance is shown as a function of the parameter space using a fixed $T_{\text{coh}} =$ 432 s and T_{obs} = 0.5 days and a CR_{thr} = 5. The plots show the result using the noise curves of LIGO Livingston, Hanford and Virgo interferometers O3brepresentative sensitivities, as in Ref. [\[14\]](#page-15-3), as well as those for the next-generation detectors like Einstein Telescope (ET) [\[99,](#page-18-0) [100\]](#page-18-1) and Cosmic Explorer (CE) [\[101–](#page-18-2)[103\]](#page-18-3) and current detector's planned upgrades (Advanced LIGO plus $-A+$) [\[104\]](#page-18-4). These results indicate that the Galactic Center, situated at a distance of $d_{\rm GC} = 8$ kpc [\[63,](#page-16-11) [105–](#page-18-5) [107\]](#page-18-6), is already reachable in a fraction of the parameter space, with current generation detectors. However, because the Doppler correction is not applied due to the relatively short duration of T_{coh} , the search remains inherently omnidirectional.

VI. TESTS WITH SIMULATED SIGNALS

The injection campaign is a fundamental aspect of addressing the pipeline's capability to detect our signals. The primary objective is to validate the method and its implementation, estimate its sensitivity comparing it to the theoretical one discussed in Sec. [V,](#page-8-0) and measure the pipeline's efficiency. All the simulated signals will be injected in real detector data.

We randomly inject signals with starting frequency in the range $20 - 250$ Hz and a chirp mass range of 10^{-6} – 10^{-3} M_{\odot} . We fix the distance in this case to 1 kpc, but the strain, h_0 , will be different for each case as it strongly depends on the initial frequency and chirp mass. We use real data from the LIGO Livingston and Hanford O3 run, divided into two segments of 0.5 days each for the analysis. The reference time of the signals selected is at the beginning of the run, starting at a GPS time of 1238198418 s.

A total of 10, 000 signals are injected sampled loguniformly in initial frequency and chirp mass, uniformly in the polarization angle ψ , and the cosine of the inclination of the orbit, $\cos \iota$, relevant for the antenna patterns and amplitude of the signal that reaches the detector [\[91\]](#page-17-16). The resulting strain will range between 7.6×10^{-27} and 4.6×10^{-23} . We assume a fixed sky position corresponding to the GC.

We examine four different cases to assess the impact of using data from additional interferometers or extending the analysis duration to multiple chunks of duration $T_{\rm obs}$. These are:

- Case 1: Only LIGO Livingston data, for a total analysis time of 0.5 days.
- Case 2: Only LIGO Livingston data, for a total analysis time of 1 days (2 contiguous chunks of duration T_{obs}).
- • Case 3: LIGO Livingston and LIGO Hanford data, for a total analysis time of 0.5 days.
- Case 4: LIGO Livingston and LIGO Hanford data, for a total analysis time of 1 days (2 contiguous chunks of duration T_{obs}).

The search is performed with the grid with variable $T_{\rm coh}$ described in Sec. [III E,](#page-6-3) as it is the most computationally inexpensive. A plot showing the recovered injections is displayed in Fig. [10](#page-10-1) alongside the theoretical limits of the search. The lower limit is governed by the 95% confidence level minimum detectable strain, addressed in Sec. [V,](#page-8-0) while the upper one is dictated by the maximum value of the variable ξ used for the search.

Several factors can explain recovered candidates below the 95% confidence level sensitivity curve. First, noise artifacts in the data can occasionally mimic true signals, passing through the detection pipeline and appearing below the sensitivity threshold. If this were the case, these candidates would likely be discarded in the postprocessing and follow-up steps, which have not been applied to the candidates in Fig. [10.](#page-10-1) Second, the formula in Eq. [\(17\)](#page-8-1), is directly applicable for the case of standard monochromatic CW signals and, despite the method described here has a similar statistical foundation as the work in [\[91\]](#page-17-16), the difference in signal modeling and signal correction might impact the final result leading to the recovery of signals at lower amplitudes than expected.

In any case, the analytical estimation and the one computed with the injections are in good agreement. Some signals are missed towards the high end of the frequency spectrum. The main reason for missing such signals is that the frequency evolution is so high that it can get out of the data frequency band being analyzed.

To evaluate the impact of using data from additional detectors or extending the analysis duration, we will use different metrics to evaluate the performance of our recovery process. To do so we need to quantify the true positives (TP), false positives (FP), and false negatives (FN).

One of such metrics is the F_1 score, defined as

$$
F_1 = \frac{2 \text{ TP}}{2 \text{ TP} + \text{FP} + \text{FN}},\tag{19}
$$

which equally weights the precision, i.e. the fraction of true positives over the recovered signals $TP/(TP+FP)$, and the recall (or true positive rate (TPR)) which is given by the fraction of injected signals that were correctly recovered $TP/(TP+FN)$.

A process with a high F_1 value is generally considered better-performing. In Fig. [11a,](#page-11-0) various values of the F_1

FIG. 9. Maximum reachable distance computed using Eq. [\(18\)](#page-9-1) for the LIGO and Virgo detectors using the O3b noise curves, design A+, design CE and design ET, $T_{\text{coh}} = 432$ s and $T_{\text{obs}} = 0.5$ days. The black line indicates where $d = 8$ kpc, the distance to the GC.

FIG. 10. Recovered injections for (Case 1) along the theoretical limits based on the sensitivity of the method and the maximum ξ searched.

score are presented as a function of the CR threshold, CR_{thr} . As expected, for high CR thresholds, the number of recovered injections reduces. But this reduction is compensated by the highest confidence in the detections. Case 4 is the one displaying a better F_1 , indicating that is the best-performing at recovering the true positives and reducing the false positives. It is also observed that there is a maximum value of the F_1 score for a given CR_{thr} . This occurs because, while increasing this threshold statistic reduces the number of false positives, it also decreases the number of true positives recovered. At a certain point, the reduction in false positives no longer compensates for the loss of true positives, leading to a decline in the overall F_1 score as too many signals are missed.

Similarly, a high TPR indicates that the process is better at capturing TP and minimizing FN. We display in Fig. [11b](#page-11-1) the values of the TPR for different values of the critical ratio threshold. As seen with the F1 score, the more information is added (from another interferometer and/or from another piece of time) the more efficient is the selection process. At the same time, when the CR_{thr} is increased, the TPR decreases. Being more restrictive with the selection criterion has as a consequence missing more injections while reducing the number of false positives.

Lastly, we can compute the detection efficiency by estimating the fraction of recovered signal, as a function of the the signal strain. This is displayed in Fig. [12](#page-11-2) for the two limiting cases (Case 1) and (Case 4). As expected, adding the information across various detectors as well as more data chunks, increases the detection efficiency.

VII. CONCLUSIONS

In this work, we have presented a novel semi-coherent method for detecting gravitational waves emitted by inspiraling binary systems of light compact objects, such as

FIG. 11. F1 score and true positive rate computed for the various cases with the injection set as described in the main text.

FIG. 12. Efficiency as a function of the strain of the signal for two of the cases of the injections.

primordial black holes. The method is based on the heterodyne correction and includes a customized grid construction in the parameter space, which significantly reduces the computational cost while preserving high sensitivity. This is achieved by exploiting parameter degeneracies that characterize the gravitational wave signal. Our injection campaign, conducted using real LIGO O3 data, has demonstrated the effectiveness of the method, successfully recovering simulated signals across a broad parameter space. Furthermore, the results align well with theoretical sensitivity predictions, underscoring the method's robustness and practical utility for future gravitational wave searches.

ACKNOWLEDGEMENTS

We would like to thank Cristiano Palomba for the valuable discussions at the early stages of the project. This research has made use of data or software obtained from the Gravitational Wave Open Science Center (gwosc.org), a service of the LIGO Scientific Collaboration, the Virgo Collaboration, and KAGRA. This material is based upon work supported by NSF's LIGO Laboratory which is a major facility fully funded by the National Science Foundation, as well as the Science and Technology Facilities Council (STFC) of the United Kingdom, the Max-Planck-Society (MPS), and the State of Niedersachsen/Germany for support of the construction of Advanced LIGO and construction and operation of the GEO600 detector. Additional support for Advanced LIGO was provided by the Australian Research Council. Virgo is funded, through the European Gravitational Observatory (EGO), by the French Centre National de Recherche Scientifique (CNRS), the Italian Istituto Nazionale di Fisica Nucleare (INFN) and the Dutch Nikhef, with contributions by institutions from Belgium, Germany, Greece, Hungary, Ireland, Japan, Monaco, Poland, Portugal, Spain. KAGRA is supported by Ministry of Education, Culture, Sports, Science and Technology (MEXT), Japan Society for the Promotion of Science (JSPS) in Japan; National Research Foundation (NRF) and Ministry of Science and ICT (MSIT) in Korea; Academia Sinica (AS) and National Science and Technology Council (NSTC) in Taiwan. Appendix A: Limits on the coherence time

In this Appendix, the various limits, either upper or lower, that can be considered for T_{coh} are discussed.

1. Maximum coherence time

One potential limit on the coherence time is settled by the statistics used and the resolution of the timefrequency map we want to achieve. The statistic is originally binomial but has a Gaussian approximation under the central limit theory validity. The time resolution of the peakmap is set by the coherence time, which also sets the frequency resolution of the map as $1/T_{\text{coh}}$. To preserve the Gaussian approximation for the peak number counts when dealing with a binomial distribution, the following condition must be met given the number N_t of FFTs: $N_t \min(p_0, 1 - p_0) > z^2$, where z is the desired z-score and p_0 the probability of success of the binomial distribution (i.e. the probability of finding a peak which is $p_0 = 0.0755$ as in [\[91\]](#page-17-16)). This ensures that the data is not too skewed and there are enough points for the approximation to be valid. Typically, the approximation is considered correct for $z^2 > 5$, corresponding to a probability coverage of $P(-z < X < z) = 0.97465$ for $z^2 = 5$ or 0.99842 for $z^2 = 10$. This leads to a limit on the minimum number of FFTs to use as $N_t = 60$ for $z^2 = 5$ and $N_t = 130$ for $z^2 = 10$. In our case, since we assume $T_{\text{obs}} = 0.5$ days, it seems reasonable to use a value in between, for example, $N_t = 100$ FFTs for the time resolution of the peakmap. This automatically translates into a maximum limit on the coherence time as $T_{\text{coh}} = T_{\text{obs}}/N_t$ which brings $T_{\text{coh}} = 432$ s.

Other restrictions for the maximum value of the FFT must be considered if we use longer T_{obs} . One natural restriction to the T_{coh} is given by the duration of the sidereal day $T_{\text{sid}} \simeq 86164$ s. The sidereal modulation, which can be appreciated for signals integrated over coherence times approaching T_{sid} , produces a splitting of the intrinsic signal frequency f_0 into five components: $f_0 \pm lT_{\text{sid}}^{-1}$ with $l = 0, 1, 2$. If this modulation is not properly considered, the signal might be undetected [\[108–](#page-18-7)[110\]](#page-18-8). Another limitation to consider is the Doppler modulation. The grid construction for ξ only considered the frequency modulation due to the spin-up without the Doppler contribution. Therefore, we need to ensure that, after the spin-up modulation is removed, a signal stays in a single frequency bin during the time T_{coh} as discussed in [\[111\]](#page-18-9):

$$
T_{\text{coh}} \le T_{\oplus} \sqrt{\frac{c}{4\pi^2 R_{\oplus} f_0}} \approx 10^4 \text{ s } \sqrt{\frac{100 \text{ Hz}}{f_0}} ,\qquad(A1)
$$

where T_{\oplus} is Earth's period of rotation and R_{\oplus} is the rotational radius at the antenna's latitude. For frequencies around 300 Hz, the maximum allowed coherence time is approximately 5000 s. We have also assessed the impact of the Doppler effect over the entire observation period T_{obs} for signals at our maximum targeted frequencies (300 Hz). The maximum Doppler shift is always smaller than the minimum frequency bin used in our search (i.e. 1/432 Hz) so we conclude that the Doppler modulation does not impact this specific search setup but is important to consider for future searches.

2. Minimum coherence time

The error of the estimators $\hat{\mu}$ and $\hat{\sigma}^2$ used to compute the CR can also be used to establish a minimum value of the coherence time. The standard error (SE) of the mean estimator, normalized by its true value, can be computed as

$$
SE_{\hat{\mu}} = \frac{\sigma}{\mu \sqrt{N_f}}.
$$
 (A2)

In this case, the values of μ and σ are known from the binomial distribution that this random variable follows and equal $\mu = N_t p_0$ and $\sigma = \sqrt{N_t p_0 (1 - p_0)}$ [\[91\]](#page-17-16). This states that

$$
SE_{\hat{\mu}} = \sqrt{\frac{1 - p_0}{N_{\text{tot}} p_0}},
$$
\n(A3)

which does not depend on T_{coh} . This is because $N_{tot} =$ $N_fN_t = \Delta f T_{\text{coh}} \times T_{\text{obs}}/T_{\text{coh}} = \Delta f T_{\text{obs}}.$ The term $\Delta f =$ $f_{\text{max}} - f_{\text{min}}$ denotes the bandwidth of the analysis.

The other error that needs to be taken into account is that of estimating the variance. The variance of the sample variance estimator is

$$
\text{Var}[S^2] = \frac{1}{N_f} \left(\mu_4 - \frac{N_f - 3}{N_f - 1} \mu_2^2 \right), \quad (A4)
$$

where μ_i indicates the *i*th central moment. For the binomial distribution here considered, $\mu_2 = \sigma^2$ and $\mu_4 =$ $N_t p_0(1-p_0)[1+(3N_t-6)p_0(1-p_0)]$. This leads to a SE (which we define as the standard deviation of the error of the variance divided by the true variance) of

$$
SE_{\hat{\sigma}^2} = \frac{\sqrt{\mathbb{V}\text{ar}[S^2]}}{\sigma^2},\tag{A5}
$$

where we have used the fact that S^2 is an unbiased estimator of σ^2 . This error depends on the coherence time

so another choice to set the minimum coherence time is to ensure that both errors are at an acceptable level. The one of the mean is constant and does not set any constraint, but the one of the variance does increase the smaller the coherence time gets and can be used to set the lower limit. In Fig. [13](#page-13-1) the evolution of both errors as a function of T_{coh} for $T_{\text{obs}} = 0.5$ days and $\Delta f = 100$ Hz is shown. For this choice of parameters, setting a maximum error of 10% would imply a minimum coherence time of \sim 1.7 s.

FIG. 13. Evolution of the standard error for the estimators of the mean and variance for T_{coh} for $T_{\text{obs}} = 0.5$ days and $\Delta f = 100$ Hz.

Appendix B: Pseudo-codes for the grid construction

In this Appendix, the pseudo-codes showing the detailed steps of the different algorithms explained in Secs. [III E](#page-6-3) and [III F](#page-6-4) are presented. The one showing how the grid in ξ is constructed with a variable coherence time is displayed in Alg. [1](#page-14-8) while the one for a fixed coherence time in Alg. [2.](#page-14-7)

For both cases, the output is a collection of pairs of (f_0, \mathcal{M}_c) that comprise the grid, and the vector of coherence times, T_{coh} , for each value of ξ . The variable coherence time algorithm also returns the vector of ξ values that are assigned during the construction of the grid.

1. Variable T_{coh}

The idea behind this algorithm is the following:

1. First, define the limits on the new variable, $\xi_{\text{min}}, \xi_{\text{max}}$ and on the frequency $f_0^{\text{min}}, f_0^{\text{max}},$ which will set the overall parameter space to be searched. Set $\xi_0 = \xi_{\text{min}}$ as the first element to start the iteration.

2. For the iso- ξ line, find the point that allows to have a longer T_{coh} . This is equivalent to finding the signal that has less frequency residual with all the rest of the signals that lie on the same iso- ξ curve. To do so, we recast it into the following optimization problem for a given ξ_i :

$$
\begin{aligned}\n\min_{f_0} \quad & \max(\mathcal{G}(\xi, f_0, f_0^{\min}), \mathcal{G}(\xi, f_0, f_0^{\max})) \\
\text{s.t.} \quad & f_0 \in [f_0^{\min}, f_0^{\max}]\n\end{aligned}
$$

This optimization problem tries to minimize the maximum frequency deviation. Since the difference between two signals increases the further away they are along the same iso- ξ curve, it is enough to compare each point to the signals that have the minimum and maximum frequencies, as they are the most limiting cases.

3. Once the optimal point has been found, the cost function value, \hat{G} , represents the maximum variation of frequency between any two signals. Therefore, we set the coherence time, as $T_{\text{coh}} = 1/\mathcal{G}$, which ensures that all frequency modulation is going to be contained within a single frequency bin.

4. Prepare the next iteration by setting $i = i + 1$ and the next value of the ξ variable as $\xi_i = \xi_{i-1} +$ $1/T_{\rm coh}$.

5. Check if $\xi_i < \xi_{\text{max}}$, for which one must return to step 2, or finish the code if either $1/\tilde{G} < T_{\text{coh}}^{\text{min}}$ or $\xi_i > \xi_{\text{max}}$ are true.

Using this approach and setting $f_0^{\text{min}} = 10$ Hz, $f_0^{\text{max}} =$ $4096 \text{ Hz}, \, \mathcal{M}^{\rm min}_{c} = 10^{-6} \, \, M_{\odot}, \, \mathcal{M}^{\rm max}_{c} = 10^{-3} \, \, M_{\odot}, \, T^{\rm max}_{\rm coh} =$ 432 s, $T_{\text{coh}}^{\text{min}} = 1.7$ s, $\xi^{\text{min}} = 10^{-8}$ Hz, $\xi^{\text{max}} = 10^{\circ}$ Hz, the grid displayed in Fig. [7](#page-7-4) is obtained. It contains 851 points in total.

2. Fixed T_{coh}

The idea behind this algorithm is the following:

1. First, define the limits on the new variable, ξ_{\min}, ξ_{\max} , on the initial frequency f_0^{\min} , f_0^{\max} , and on the chirp mass \mathcal{M}^{\min}_{c} , \mathcal{M}^{\max}_{c} , which will set the overall parameter space to be searched; as well as the target coherence time, $T_{\rm coh}^{\rm tar}$. Set vector of ξ values can be already computed as it is evenly spaced with an increment of $1/T_{\text{coh}}^{\text{tar}}$.

2. For the iso- ξ line, find whether with $T_{\rm coh}^{\rm tar}$, a single point can absorb all the frequency evolution of the signals contained in the iso- ξ line. We do this by checking whether $\mathcal{G}(\xi[i], f_0[k], f_0^{\max}) \leq 1/T_{\text{coh}}^{\text{tar}}$. If this relation is hold, we then place a point at f_0^{max} and the corresponding chirp mass for that given initial frequency and ξ .

Algorithm 1: Pseudo-code for the construction of the grid with a variable FFT length

 $\begin{split} \textbf{Input} &\;\; :\textit{f}_{0}^{\min} \; ;\textit{f}_{0}^{\max} \; ;\textit{\xi}_{\min} \; ;\textit{\xi}_{\max} \; ;\textit{T}_{\mathrm{coh}}^{\max} \; ;\textit{T}_{\mathrm{coh}}^{\min} \ \textbf{Output:} \; \textit{T}_{\mathrm{coh}} \in \mathbb{R}^{n_p};\textit{f}_{0} \in \mathbb{R}^{n_p} \; ;\mathcal{M}_{c} \in \mathbb{R}^{n_p} \; ;\textit{\xi} \in \mathbb{R}^{n_p} \end{split}$ $\xi[1] \leftarrow \xi_{\min}$ $i \leftarrow 1$ while $\xi[i] < \xi_{\rm max}$ do Solve the following optimization problem: $\min_{f_0} \quad \max(\mathcal{G}(\xi[i], f_0, f_0^{\min}), \mathcal{G}(\xi[i], f_0, f_0^{\max}))$ s.t. $f_0 \in [f_0^{\min}, f_0^{\max}]$ The solution is $\tilde{\mathcal{G}} = \mathcal{G}(\xi[i], \tilde{f}_0, f_0^{\min})$ found at \tilde{f}_0 $f_0[i] \leftarrow f_0$ $\mathcal{M}_c[i] \leftarrow \mathcal{M}_c(\xi[i], \tilde{f}_0)$ if $1/\tilde{\mathcal{G}} \ge T_{\rm coh}^{\rm max}$ then $T_{\text{coh}}[i] \leftarrow T_{\text{coh}}^{\text{max}}$ else if $1/\tilde{\mathcal{G}} < T_{\mathrm{coh}}^{\mathrm{min}}$ then | break else $T_{\text{coh}}[i] \leftarrow 1/\tilde{\mathcal{G}}$ end $i \leftarrow i + 1$ $\xi[i] \leftarrow \xi[i-1] + 1/T_{\text{coh}}[i]$ end $n_p \leftarrow i$

3. If that relation is not maintained, we need to place more than one point along the iso- ξ line to contain all possible frequency evolution residuals inside a single frequency bin. We do so by solving the following optimization problem:

$$
\begin{aligned}\n\max_{f_0} \quad & f_0 \\
\text{s.t.} \quad & f_0 \in [f_0[k], f_0^{\text{max}}] \\
& \quad \mathcal{G}(\xi[i], f_0[k], f_0^{\text{max}}) \le 1/T_{\text{coh}}^{\text{tar}}\n\end{aligned}
$$

This optimization problem tries to place the next point as far away from the last point in the same iso-ξ (thus maximizes f_0) while making sure that

the residual between this new point and the last one placed is below $1/T_{\text{coh}}^{\text{tar}}$. This optimization problem has its solution on the boundary of the feasible region, as the target function is monotonically increasing. This means that the computational cost can be slightly reduced by finding the point that satisfies $G(\xi[i], f_0[k], f_0^{\max}) = 1/T_{\text{coh}}^{\text{tar}}$ to avoid the optimization problem as, typically, the solution of the nonlinear equation will be faster.

4. Go to point 2 until all iso- ξ curves have been looped for.
